

Über dieses Buch

Dies ist ein digitales Exemplar eines Buches, das seit Generationen in den Regalen der Bibliotheken aufbewahrt wurde, bevor es von Google im Rahmen eines Projekts, mit dem die Bücher dieser Welt online verfügbar gemacht werden sollen, sorgfältig gescannt wurde.

Das Buch hat das Urheberrecht überdauert und kann nun öffentlich zugänglich gemacht werden. Ein öffentlich zugängliches Buch ist ein Buch, das niemals Urheberrechten unterlag oder bei dem die Schutzfrist des Urheberrechts abgelaufen ist. Ob ein Buch öffentlich zugänglich ist, kann von Land zu Land unterschiedlich sein. Öffentlich zugängliche Bücher sind unser Tor zur Vergangenheit und stellen ein geschichtliches, kulturelles und wissenschaftliches Vermögen dar, das häufig nur schwierig zu entdecken ist.

Gebrauchsspuren, Anmerkungen und andere Randbemerkungen, die im Originalband enthalten sind, finden sich auch in dieser Datei – eine Erinnerung an die lange Reise, die das Buch vom Verleger zu einer Bibliothek und weiter zu Ihnen hinter sich gebracht hat.

Nutzungsrichtlinien

Google ist stolz, mit Bibliotheken in partnerschaftlicher Zusammenarbeit öffentlich zugängliches Material zu digitalisieren und einer breiten Masse zugänglich zu machen. Öffentlich zugängliche Bücher gehören der Öffentlichkeit, und wir sind nur ihre Hüter. Nichtsdestotrotz ist diese Arbeit kostspielig. Um diese Ressource weiterhin zur Verfügung stellen zu können, haben wir Schritte unternommen, um den Missbrauch durch kommerzielle Parteien zu verhindern. Dazu gehören technische Einschränkungen für automatisierte Abfragen.

Wir bitten Sie um Einhaltung folgender Richtlinien:

- + *Nutzung der Dateien zu nichtkommerziellen Zwecken* Wir haben Google Buchsuche für Endanwender konzipiert und möchten, dass Sie diese Dateien nur für persönliche, nichtkommerzielle Zwecke verwenden.
- + *Keine automatisierten Abfragen* Senden Sie keine automatisierten Abfragen irgendwelcher Art an das Google-System. Wenn Sie Recherchen über maschinelle Übersetzung, optische Zeichenerkennung oder andere Bereiche durchführen, in denen der Zugang zu Text in großen Mengen nützlich ist, wenden Sie sich bitte an uns. Wir fördern die Nutzung des öffentlich zugänglichen Materials für diese Zwecke und können Ihnen unter Umständen helfen.
- + *Beibehaltung von Google-Markenelementen* Das "Wasserzeichen" von Google, das Sie in jeder Datei finden, ist wichtig zur Information über dieses Projekt und hilft den Anwendern weiteres Material über Google Buchsuche zu finden. Bitte entfernen Sie das Wasserzeichen nicht.

ALMROTH WRIGHT by LEONARD COLEBROOK, FRs

Provocative Doctor and Thinker

Almroth Wright was one of the great pioneers. His name will be linked with those of Pasteur, Koch, Ehrlich, and his own pupil Fleming. He was the modern father of immuno-therapy—that branch of medicine which started with Jenner and was forgotten for a century until it was resuscitated by Wright himself at Netley when he discovered anti-typhoid inoculation. His Life, written by his friend and pupil Leonard Colebrook, gives a clear picture of the man. We see him in all his moods; his intense longing to find methods to ease the world of pain, his altruism, his belligerency, his view of women's suffrage, his skirmishes with his fellow countryman, Bernard Shaw, his contact with the Great War. 218

ALETHETROPIC LOGIC by Sir ALMROTH WRIGHT, MD SCD FRs

Presented by GILES J. ROMANES, MA MRCS DOMS

All through his long life Sir Almroth was working out a system of logic which he felt would clarify men's minds so that they saw the truth clearly, undimmed by errors of training and mental outlook. These studies are here presented posthumously. 253

IRON WITHOUT IRRITATION

'Fergon' (ferrous gluconate) does not produce the gastrointestinal disturbances often associated with iron therapy. This is particularly valuable in hypochromic anæmia of pregnancy since patients who cannot tolerate other iron preparations are able to take 'Fergon' without discomfort. Absence of irritant effects also ensures maximum absorption and utilisation of iron with a consequently rapid rise in the hæmoglobin rate.

PACKINGS: tablets gr. 5 in bottles of 100 and 1,000; liquid (6%), for infants and young children, in 4 oz. and 80 oz. bottle.

* The reduced basic N.H.S. cost of one week's treatment with 'Fergon' tablets is 8d. The basic N.H.S. price of 'Fergon' liquid is 3s. per 4 oz. bottle

Sir RUSSELL BRAIN

M.A., D.M. Oxfrd, LL.D. Wales, P.R.C.P., F.R.C.P.E.,
F.R.C.P.I.PHYSICIAN TO THE LONDON HOSPITAL AND TO MAIDA VALE
HOSPITAL FOR NERVOUS DISEASES*With illustrations on plate*

I HAVE chosen to talk about a particular kind of intervertebral disc lesion for several reasons. Degeneration of the intervertebral discs is responsible for a very large amount of pain, suffering, and disability, which ranges from episodes which, however painful, are comparatively short-lived, though they may be recurrent, to permanent incapacity of the most severe and disabling kind. Moreover, intervertebral disc degeneration is, on the whole, a disorder of the second half of life, occurring particularly in the fifth and sixth decades; hence, as we have an ageing population, it is steadily increasing in frequency and in social importance.

My interest in the subject has been primarily concerned with the effects of the disc degeneration upon the nervous system; but the neurological manifestations, of course, are end-results, which often declare themselves only after the disc lesion has been present for many years; so if we are to prevent these most disabling consequences of disc degeneration we must know far more than we do about the aetiology of both. For even when the disc degeneration has already occurred and brought the patient to the doctor on account of pain in the spine or its effect upon the nerve-roots or the spinal cord, we still know far too little about what is really happening, and often we have not sufficient knowledge upon which to base a rational therapy. Our problem, then, is to correlate the patient's symptoms and signs with the radiological appearance of the affected portion of the spine and both with the pathological changes which are responsible for the symptoms. For example, the patient's symptoms may be acute and severe, yet it may be difficult to detect any X-ray abnormality. At the other extreme are patients with gross radiological changes but no symptoms at all. In between fall patients who seem at first sight the easiest to understand—namely, those who have chronic symptoms associated with chronic changes as shown by the X rays; but it is equally likely that another patient with X-ray films which show apparently similar chronic changes will come to the doctor because of symptoms which are acute. These discrepancies, which could easily be multiplied, show how difficult it is in many cases to form an opinion as to the precise nature of the pathological change which is responsible for the current symptoms; and without that knowledge treatment must be, as we must admit it often is, largely empirical. Hence the differing views about the value of, and indications for, physiotherapy of various kinds, immobilisation, traction, manipulation, and operation.

Nomenclature in Relation to Pathology

I do not propose to deal with those lesions of the intervertebral discs which are produced by their invasion by neoplasms or by infection: I shall confine myself to the changes which have come to be grouped under the term "spondylosis," which, of course, implies that the lesions are degenerative and not inflammatory. This term, however, is itself deceptively simple, if it is taken to mean that we are dealing with a single pathological

process; and current terminology reflects the confusion in our ideas about the pathogenesis of what is called spondylosis. Sometimes the term "herniation" of the intervertebral discs is used and sometimes the term "protrusion"; and it is widely believed that the two are synonymous. Frykholm (1951b) points out that

"... the large amount of data available concerning the thoraco-lumbar discs cannot... be used indiscriminately to explain the pathologic condition affecting the cervical discs. The two groups differ too much both anatomically and with regard to the forces to which they are subjected. This is also apparent from the fact that in the cervical region soft nuclear herniations, similar to those in the lumbo-sacral region, are relatively infrequent compared to the hard and calcified types."

Nevertheless I believe that the pathological classification of cervical disc protrusions which Frykholm has himself proposed is equally applicable to intervertebral disc protrusions occurring lower in the spine, provided suitable qualifications as to their pathogenesis are introduced.

In 1948 I suggested (Brain 1948) a distinction between two main types of intervertebral disc protrusion—(1) nuclear herniations and (2) annular protrusions—and this has been confirmed by Frykholm.

Nuclear herniation probably starts with swelling of the nucleus. The annulus, which is encroached upon by the expanding nucleus, undergoes fibillary degeneration. Its inner fibres emerge with the nucleus while its outer fibres disintegrate, as the result of which nuclear material may be extruded into one or other intervertebral foramen, or more dorsally. Bull (1948) has calculated that the total volume of the nucleus pulposus in the cervical region corresponds to that of a red currant. Theoretically, therefore, this would be the maximal size of a complete nuclear herniation. Frykholm points out, however, that the mass always contains fragments of the annulus, and in addition it has a tendency to grow in size through a process of metaplasia and the addition of new tissue. The nuclear material is replaced by fibrous and cartilaginous elements and may show evidence of inflammatory reaction. Calcification or ossification may supervene. The mass finally presents the appearance of a well-defined tumour.

The production of an *annular protrusion* is different. Owing to various factors, of which age is probably the most important, the intervertebral disc becomes dehydrated and loses its elasticity. As a result it collapses and the annulus bulges in all directions. Local bulgings may also occur at some point if the fibres of the annulus are less resistant. The protruded material becomes vascularised and its fibrous elements are increased in the same manner as in the nuclear herniation. Similarly the added tissue increases the size of the original protrusion, and again calcification or ossification may occur.

So far we have been describing the alterations which occur in the intervertebral discs themselves, but the impairment of their normal functions leads to reactive changes in the bodies of the adjacent vertebrae. These are stimulated to new bone formation—i.e., the production of the osteophytes which tend to fuse with the disc protrusions. Frykholm distinguishes two types of osteophytes: the one which is produced in the manner just described he calls marginal lipping, which may be either localised or affect the entire circumference of the vertebral margins. Ventral spurs, on the other hand, are anatomically related to the anterior longitudinal ligaments, and, according to Schmorl (1929), they are the result of increased strain on this ligament, the fibres of which are firmly attached to the vertebral margins. Furthermore, the collapse of a disc also results in subluxation of the corresponding intervertebral joints with secondary osteophyte formation on the articular processes, which leads to further narrowing of the intervertebral foramina.

*The Heberden Oration for 1953, delivered before the Heberden Society in London on Dec. 4. Published also in the March issue of the *Annals of the Rheumatic Diseases*.

If, as I believe, this account is fundamentally correct it follows that "intervertebral disc protrusion" is a name applied to two conditions which are pathologically distinct: one type of protrusion is the product of a nuclear herniation while the other is not a herniation but an annular protrusion. A nuclear herniation which has occurred acutely and which is observed before it has had time to harden may be relatively soft: later, calcification and ossification, together with the reactive bony changes in the adjacent vertebræ, may make it extremely difficult to distinguish from an annular protrusion which is the result of disc degeneration. But the matter is more complicated than that, because the beginnings of a nuclear protrusion, which goes no further than tearing some of the fibres of the annulus, may interfere with the function of the intervertebral disc in the same way as primary degeneration and excite the same reactions from adjacent vertebræ, so that the changes which tend to produce nuclear protrusion are probably one cause of disc degeneration. Finally, be it noted, intervertebral disc degeneration may occur without leading to protrusion.

Thus when we use the term spondylosis we are describing something which is not pathologically homogeneous: we are dealing in fact with a spine which manifests the end-results of either or both of two distinct pathological processes, nuclear herniation and annular protrusion. To some extent radiography is responsible for suggesting that spondylosis is a single disorder, since in the late stages it is not, as far as I know, possible to distinguish the one type from the other by means of X rays. If we are to study the natural history of what is called spondylosis, however, we cannot confine ourselves to the end-results, but we must also take into account the acute nuclear herniation with which one type of spondylosis begins.

Problems of Ætiology

We see, therefore, how complex the causation of spondylosis may be. How large a part does trauma play? In our series of cases of cervical spondylosis (Brain, Northfield, and Wilkinson 1952) two-thirds of our patients gave no history of trauma, and only 6 out of 45 gave a history of trauma which could possibly have contributed to the causation of the disorder. Nevertheless the frequency with which disc degeneration is limited to a single disc—as was the case in 18 out of 38 of our patients with cervical spondylosis, and is very common in the lumbar spine—suggests that local causes are at least as important as a diffuse degenerative process, and a minor trauma which may have started the process years previously may easily have been forgotten. The rôle of trauma in producing acute disc protrusion in the lumbar region is well recognised, and it may often exacerbate a pre-existing one.

The wear and tear of normal spinal movements may be a contributory factor, especially when disc degeneration has already begun; and congenital abnormalities, especially Klippel-Feil fusion, throw an added strain on adjacent articulations. Undoubtedly the most important causal factor is the biochemical change in the intervertebral discs which occurs with ageing and is associated with a loss of water (Collins 1949, Sylvén et al. 1951): and prevention of spondylosis must largely depend upon an elucidation of this process. The importance of disc degeneration is well illustrated by those patients who exhibit spondylosis from top to bottom of the spine and by the frequency with which symptoms

of cervical and lumbar spondylosis occur in the same individual.

The Pathology of the Nerve-roots in Cervical Spondylosis

We owe much of our knowledge of the structure of the coverings of the cervical spinal nerve-roots, and their relationship with the cervical vertebræ, to the careful studies of Frykholm (1951c). The cervical intervertebral foramina are bounded above and below by the pedicles of the two adjacent vertebræ. The radicular nerves are situated in the foramina, and the dorsal root ganglia lie just outside in the gutter of the transverse process. The posterior wall of the foramen is formed by the superior articular process of the vertebra below, which in turn is covered posteriorly by the inferior articular process of the vertebra above. The ventral delimitation of the foramen is effected partly by the two adjacent vertebral bodies and partly by the dorsolateral rim of the intervertebral disc. This is termed the uncinæ process, and there has been some discussion as to whether between the uncinæ process of the lower vertebra and the corresponding facet of the vertebra above there is a true joint, as Luschka supposed. This has been called the uncovertebral joint and the neurocentral joint; but some, including Frykholm (1951b) believe that what has been regarded as a joint cavity is merely part of the annulus of the intervertebral disc.

The rather complicated structure of the investment of the radicular nerves can be best understood by reference to a diagram (fig. 1). Opposite each foramen the dural sac has a small infundibular extension, the dural root-pouch, or axillary pouch of some authors. By means of the funnel-like shape of the pouches, each nerve-root is

Fig. 1.—Drawing showing principal features of the anatomy of cervical nerve-roots and their dural and arachnoid investments (Frykholm 1951c). For details see text.

conveyed in a smoothly curved course to the point at which it leaves the dural sac. At the bottom of the root-pouches there are two openings, the dural root-ostia, one ventral and one dorsal, which are separated by a small dural septum, the inter-radicular septum. Each root-ostium leads into an individual root-sleeve, of which there are consequently two, one dorsal and one ventral. The root-sleeves, which are lateral extensions of the dural sacs, are separated by a small cleft known as the inter-radicular foramen. Consequently, outside the dural sac, the dorsal and ventral roots pass through individual sheaths which are entirely separated. A tubular extension of the arachnoid membrane encloses each root in its proper root-sleeve. Between the dural sac and the dorsal root ganglion the two roots lie close together and form an anatomical entity referred to as the radicular nerve.

Fig. 2—Dissection of cervical nerve-roots in their passage through the intervertebral foramina, showing variations in shape of the dural root-pouches.

In seeking to interpret the effect of the bony changes of cervical spondylosis upon the radicular nerves it is of cardinal importance to remember that the radicular nerve normally occupies only one-fifth to one-fourth of the diameter of the foramen; hence, if the nerve lay always in the middle, considerable narrowing of the foramen could occur without producing any effect upon it. Frykholm (1951c), however, points out that the morphology of the lower cervical radicular nerves and their root-pouches is extremely variable, as illustrated by fig. 2. In early childhood the dural sac and the radicular nerves are only loosely attached to the bone. As age advances they gradually become relatively well fixed in their definite positions. In most cases the radicular nerves then take a slightly downward course and pass through the centre of their respective foramina. Variations in this arrangement may occur in normal individuals, probably as the result of disproportionate growth of the dural sac and the cord relative to the vertebral column. Displacement of the radicular nerves within the foramina may, however, occur also as the result of cervical disc degeneration quite independently of the pressure of disc protrusion, since the cord and the dural sac retain their original length while the spine is shortened owing to osteoporosis and disc degeneration. The lower cervical radicular nerves thus tend to be displaced towards the lower part of their foramina and hence become more upwardly directed. The displacement downwards also tends to distort the root-pouches, which results in sharp angulation of the nerve-roots; and at this point of angulation the roots are subjected to undue strain and increased friction with the dural lining. Frykholm points out that in consequence the segmental level of such a lesion does not necessarily correspond to a level of a disc degeneration.

Now let us consider the more direct effect of cervical intervertebral disc protrusion and the associated vertebral changes upon the nerve-roots and radicular nerves. In this connection I shall not concern myself with acute nuclear herniation, but with the end-results of disc protrusion, however produced, and disc degeneration, in cervical spondylosis. Such disc protrusions have been variously classified according to their position in the circumference of the disc, but one or more of these different types of protrusion may be encountered in the same disc, and they merge into one another. From the point of view of the radicular nerves and nerve-roots, however, the only two with which we need concern ourselves are the dorsolateral protrusion, which does not invade the intervertebral foramen but may compress the intrameningeal nerve-roots against the vertebral laminae, and the intraforaminal protrusion, which emerges from the uncinata part of the disc and compresses the radicular nerve against the articular processes (fig. 3). The mechanism of root compression, however, depends not only upon the size and location of the protrusion but also upon the angulation of the radicular nerve and its situation in the foramen. Thus, for example, a protrusion restricted to the lower part of the foramen may leave the roots quite intact if the radicular nerve is downwardly directed and situated cranially in the foramen, whereas if the nerve is caudally situated and outwardly or upwardly directed there is a much greater chance that it will be implicated. Furthermore, a protrusion which is strictly localised to the lower half of the foramen may produce a selective compression of the ventral root and leave the dorsal root intact, because the ventral root often runs along the caudal border of the dorsal root. Finally, cervical disc degeneration without protrusion may lead to marginal lipping as a result of the increased stress which falls directly

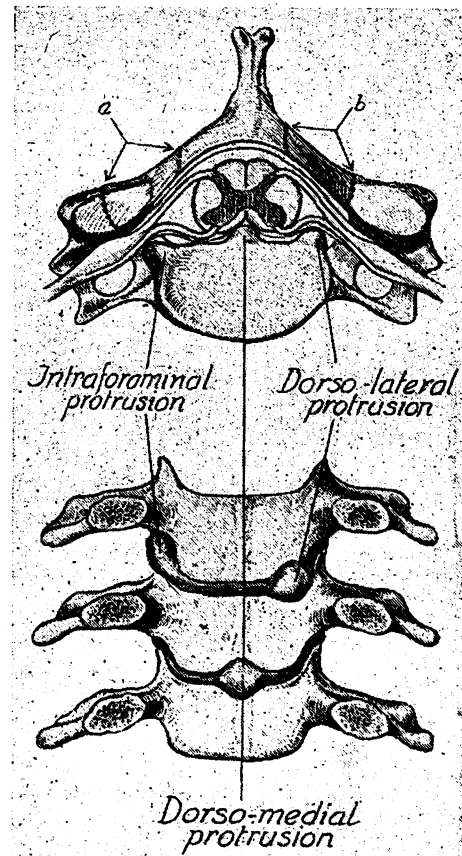

Fig. 3—Drawing (Frykholm 1951b) showing principal types of disc protrusion: (i) dorsomedial; (ii) dorsolateral; and (iii) intraforaminal.

upon the vertebra when the disc loses its shock-absorbing properties. This may cause some osteophyte formation in the anteromedial part of the intervertebral foramen. At the same time the narrowing of the disc throws an additional strain upon the corresponding intervertebral joints and that leads to secondary osteophyte formation on the articular processes, thus narrowing the foramen posterolaterally.

The pathological effects of these bony changes in the neighbourhood of the intervertebral foramen have been studied by Frykholm (1951a). In their fully developed form they consist of what he calls "root-sleeve fibrosis." This is characterised by (1) thickening and opacity of the dural root-sleeve and adjacent parts of the dural sac (i.e., the root-pouch); (2) narrowing, or complete abolition, of the dural funnel which forms the root-pouch; (3) sharpening of the upper and lower duro-radicular junction, which sometimes causes a distinct constriction or notching of the radicular nerve; (4) thickening of the dura at the root-ostia and occasionally, also, thickening of the inter-radicular septum resulting in a constricting ring of fibrous tissue around each nerve-root; (5) thickening and fibrosis of the arachnoid membrane in the neighbourhood of the root-ostia, and (6) disintegration and hyalinisation of the dural tissue involved. The chronic constriction of the nerve-roots and radicular nerve, and associated ischæmia, lead in time to the degeneration of the nerve-fibres. Frykholm points out that in many cases root-sleeve fibrosis is observed in the absence of any constriction of the corresponding foramen, though in such cases there is usually X-ray evidence of disc degeneration either at the same segmental level or at one or two levels above that of the radicular lesion. Occasionally also root-sleeve fibrosis may be present in spite of the fact that the cervical spine shows no X-ray abnormality.

Thus, cervical intervertebral disc degeneration initiates a complex and variable series of changes which may affect the nerve-roots and radicular nerve in a number of different ways which need to be assessed individually in each case. These changes may be summarised as follows:

(1) Disc degeneration affects the mobility of the cervical spine. The simplest example of this is the effect of degeneration of a single disc. Usually this greatly limits flexion and extension at the intervertebral joints between the two vertebrae separated by the affected disc. Since the main movement must now occur above and below, abnormal stresses may fall not only upon adjacent intervertebral joints but also upon adjacent radicular nerves. Exceptionally, disc degeneration leads to abnormal mobility, in which case, as a rule, the body of the upper vertebra slips forward upon that of the lower on flexion and slips back again on extension, a movement which must obviously tend to produce damage to the radicular nerves in the corresponding foramina.

(2) Narrowing of intervertebral discs shortens the cervical spine and disturbs the relation between the radicular nerves and their corresponding foramina, the lower ones, particularly, tending to rest upon the lower margins of the foramina and to be kinked over them.

(3) Disc degeneration by itself can produce lipping of the adjacent vertebral bodies and so narrow the inner margins of the intervertebral foramina, whilst increased strain upon the intervertebral articulations produces osteophytic narrowing posteriorly.

(4) All this may occur without intervertebral disc protrusion. In addition, however, a dorsolateral protrusion may compress the nerve-roots within the spinal canal, while an intra-foraminal protrusion may compress them or the radicular nerve within the foramen.

(5) All the above-mentioned processes tend to lead to root-sleeve fibrosis, the characteristic reaction of the investment of the nerve-roots and radicular nerve to chronic irritation and compression. These pathological changes, therefore, though most likely to occur in the nerve-roots which pass through the intervertebral foramina at the level of the degenerated disc, may be present also at other levels at which there is no evidence of disc degeneration.

(6) Finally, the affected nerve-roots and radicular nerves, tethered to the foramina by root-sleeve fibrosis, and lacking their normal mobility, are far more susceptible to trauma than normal nervous tissue. Consequently not only may severe and lasting radicular

symptoms be set up by head injury in such cases, but it is probable that comparatively slight trauma may be responsible for the acute onset of symptoms in patients with cervical spondylosis and of symptoms which may be multiradicular in distribution although the bony pathological changes may be limited to one intervertebral disc and its adjacent vertebrae.

The Significance and Insignificance of Radiographic Changes

We are now in a position to assess the value and limitations of radiography in the diagnosis of the radicular lesions accompanying cervical spondylosis, and also, perhaps, to clear up some of the apparent anomalies. In the radiological investigation of a patient suspected of cervical spondylosis it is usually necessary to take three lateral views (in the erect, flexed, and extended positions) as well as an anteroposterior view and right and left oblique views to show the intervertebral foramina. Without the flexed and extended lateral views it may be impossible to detect spondylolithesis (fig. 4). In addition, plain radiographs may show a narrowed intervertebral disc space indicating disc degeneration; posterior osteophytes, in the manifestation of which specially soft films may be helpful; and osteophytic invasion of the intervertebral foramina (fig. 5). It is important to bear in mind the following points in the interpretation of the X-ray appearances:

(1) A narrowed intervertebral disc space indicates disc degeneration which may or may not be associated with disc protrusion.

(2) The absence of posterior osteophytes, which are radiographically visible, does not necessarily mean the absence of a disc protrusion.

(3) A normal intervertebral foramen does not necessarily mean healthy nerve-roots or radicular nerves, for

(4) The nerve-roots may be compressed in the spinal canal by a dorsolateral disc protrusion which does not involve the foramen, or they may be the subject of root-sleeve fibrosis within a normal foramen for one of the reasons mentioned above.

(5) A narrowed intervertebral foramen does not necessarily mean that the corresponding nerve-roots or radicular nerves are compressed, since normally the nerve takes up only a small proportion of the space in the foramen and if it is centrally situated may for a long time avoid damage or even tolerate a considerable degree of compression without giving rise to symptoms.

(6) Myelography may be valuable for the purpose of showing a disc protrusion, which is not visible on the plain radiograph, or a root-sleeve fibrosis which may be demonstrable by obliteration of the root-pouch in the

myelogram although the intervertebral foramen may appear normal on the plain radiographs.

Some Radicular Syndromes of Cervical Spondylosis

I believe that the various clinical pictures described in the past as "brachial neuritis" or "brachial neuralgia" are in most cases the result of the pathological changes described by Frykholm as root-sleeve fibrosis. I shall not now retread the well-worn path of the clinical symptomatology of "brachial neuritis" but shall confine myself to a consideration of some of the less familiar clinical pictures and, in particular, those upon which light is thrown by the newer knowledge of the pathology of the condition.

Acroparæsthesiæ

Acroparæsthesiæ may be defined as unpleasant tingling sensations affecting some or all of the digits of one or both upper limbs, developing during the night and usually passing off within an hour or so of awakening and particularly liable to occur in middle-aged women. Thus defined, acroparæsthesiæ are merely a symptom, and it is inherently unlikely that a symptom of irritation of sensory nerve-fibres is characteristic of a lesion occurring at only one point in their course. I believe that acroparæsthesiæ may occur as a symptom of either (1) cervical spondylosis, (2) a costoclavicular syndrome involving particularly perhaps vasomotor elements, or (3) compression of the median nerve in the carpal tunnel. Acroparæsthesiæ, however, are so common a symptom of cervical spondylosis that all patients who complain of them should have their necks radiographed.

Pain Referred to Myotome and Sclerotome

A dermatome is the area of skin supplied by a single spinal nerve. The importance of the dermatome in neurological diagnosis has perhaps tended to obscure the fact that a spinal nerve distributes sensory nerve-fibres to muscles, bones, joints, and ligaments which have an anatomical distribution ranging widely beyond the cutaneous area innervated by the same segment. The muscles supplied by a single radicular nerve have been termed a myotome, and the bones and joints similarly supplied have been termed a sclerotome. Pain due to irritation of a spinal posterior root or radicular nerve, therefore, may irradiate widely, and this may sometimes give rise to difficulties in diagnosis. For example, both the 6th and 7th cervical radicular nerves supply sensory

fibres to the posterior cervical muscles, pectoralis major, latissimus dorsi, and serratus magnus as well as to other muscles of the trunk and upper limbs and the corresponding dermatomes. Irritation of either of these nerves may therefore cause pain referred to the neck and back and front of the chest as well as to the upper limbs, and, it has been pointed out, may suggest pain of cardiac origin.

Muscular Wasting

Muscular wasting is not usually severe as a result of the radicular lesions of cervical spondylosis, but it may be a prominent symptom and even occur in the absence of objective sensory abnormalities. It may then lead to an erroneous diagnosis of motor-neurone disease. Frykholm points out that such muscular wasting is probably due to a selective damage to the anterior spinal roots by compression arising from the lower part of the foramina. It may affect the muscles supplied from several segments or from one only.

"The Frozen Shoulder"

Pain of radicular distribution due to cervical spondylosis and referred to the shoulder is not infrequently followed by the condition known as "frozen shoulder" in which gross limitation of active and passive movements of the shoulder occurs and any attempt to move the joint causes pain. The possibility that a "frozen shoulder" is a symptom of cervical spondylosis should always be borne in mind.

Acute or Subacute Multiradicular Symptoms

As a rule the radicular symptoms of cervical spondylosis are limited to one, or perhaps two, segments. The older clinical accounts of brachial neuritis, however, usually describe pain radiating down the whole length of the arm to all the digits and associated with some degree of generalised muscular wasting, weakness, diminution of the tendon reflexes, and perhaps very diffuse cutaneous sensory loss. This clinical picture may undoubtedly occur as the result of cervical spondylosis, and even when the X-ray changes are limited to one or two intervertebral joints. As I have suggested above, the probable explanation is that in such cases root-sleeve fibrosis is much more widespread than X-ray changes would suggest, and some change—perhaps a slight trauma or even possibly exposure to cold—has intensified the lesion in most of the roots from which the brachial plexus is derived. An alternative possibility is that an acute lesion of a single root may sometimes cause pain which, owing to the considerable overlap of dermatomes, radiates to a large area of the upper limb and at the same time reflexly interferes with muscular function.

The Pathogenesis of Myelopathy in Spondylosis

Cervical spondylosis damages the spinal cord less often than the nerve-roots, but sufficiently often to make spondylotic myelopathy one of the commonest, if not the commonest, disease of the spinal cord during and after middle life. This is illustrated by the fact that 41 patients with cervical spondylosis have been admitted as inpatients to the neurological department of the London Hospital during the last two years, mostly because of myelopathy. The pathogenesis of the myelopathy, like that of the root-sleeve fibrosis, is complex, and certainly a number of factors are concerned. The most obvious is direct compression of the cord by one or more protruding intervertebral discs. When the disc protrusion is large, the cord may be compressed between it and the laminae posteriorly (fig. 6), the pressure being sufficient even to cause thinning of the laminae. Greenfield (1953), however, believes that in most cases the areas of demyelination are too limited to be explained as the result of simple compression. He thinks that compression may operate indirectly by interfering with the blood-flow through the anterior spinal artery. The blood-supply to

the spinal cord may be further impaired by narrowing of the intervertebral foramina through which the radicular arteries penetrate. Compression of the anterior spinal veins has also been regarded as a contributory factor. Stretching of the ligamenta denticulata also, in Greenfield's opinion, plays an important part, since by anchoring the spinal cord these ligaments tend to increase the effects of compression on the anterior spinal vessels. Moreover they exert tension on the lateral aspects of the spinal cord. The neck, however, is not static, but in constant movement throughout waking life, and a considerable amount of movement still occurs in a spine which is the site of severe spondylosis. As already mentioned, movement may be pathological when one body slips forward upon the one immediately below it on flexion of the neck (fig. 4). Root-sleeve fibrosis, which is invariably present to a greater or less extent in these cases, tends to anchor the roots in the foramina, and by thus limiting the mobility of the cervical cord must add to the traumatic effect of repeated movement of the neck when the cord is already compressed by a disc protrusion. All these factors combine to produce a condition which is best described as cervical myelopathy. Moreover, in the presence of cervical spondylosis, even though the spinal cord has so far apparently escaped injury, severe damage may be produced by forcible extension of the neck as the result of a blow upon the front part of the head, or even, as Symonds (1953) has shown, in the course of the administration of an anaesthetic or an operation upon the tonsils.

Symptomatology of Cervical Myelopathy due to Spondylosis

I do not propose now to discuss in detail the symptomatology of cervical myelopathy resulting from spondylosis (see Brain 1948, Brain et al. 1952), but only to draw attention to the relation between the pathology and the symptomatology, and, in particular, to try to show how the pathology explains the extremely varied clinical picture.

To simplify matters, let us consider only the factor of disc protrusion. Since disc protrusions may be single or multiple, and may occur at any, or all, levels of intervertebral discs, it is clear that any segment of the cervical cord may be compressed from the 3rd to the 8th—that is, either above or in the course of the cervical enlargement. Furthermore, a disc protrusion into the vertebral canal may be situated either in the midline or to one or other side, or be more or less continuous; and, except in extreme cases, the resulting demyelination does not involve the whole transverse extent of the cord. It is therefore easy to understand how varied is the resulting clinical picture and how many other disorders it may simulate.

Since the onset of symptoms is usually insidious, and may be either intermittently or steadily progressive, the disorder will tend to resemble those lesions of the spinal cord which occur in middle life and have these general characteristics. Muscular wasting, fasciculation, and weakness in the upper limbs, combined with spastic weakness of the lower limbs in the absence of sensory loss, may closely simulate motor-neurone disease. Weakness, numbness, and clumsiness of the upper limbs, associated with ataxic paraplegia, and perhaps some sensory loss in the lower limbs, is a clinical picture resembling disseminated sclerosis. When the damage falls chiefly upon the pyramidal tracts and the posterior columns, with which may be associated some wasting of the hands and sensory loss of glove distribution in the upper limbs, there is a considerable resemblance to subacute combined degeneration. Extramedullary tumour, intramedullary tumour, and syringomyelia may all easily be simulated. When the symptoms are those of pure bilateral pyramidal degeneration a diagnosis of

primary lateral sclerosis may be made. In some cases cervical myelopathy may for a long time cause only paraplegia without detectable abnormalities in the upper limbs, and then the cause may be thought to originate in the dorsal region of the spinal cord. Occasionally, as Symonds (1953) points out, cervical spondylosis may be the cause of quadriplegia of sudden onset, which may be permanent or, as in one recent patient of my own, brief and intermittent. Finally, to add to the hazards of diagnosis, not only may cervical spondylosis coexist with a quite independent lesion of the nervous system which is itself responsible for the symptoms, but it may sometimes be associated with some other abnormalities of the spine or of the spinal cord—particularly of congenital origin, such as congenital fusion of vertebrae, cervical spina bifida, and the Arnold-Chiari malformation—while syringomyelia and tabes may cause a cervical arthropathy which is not only difficult to distinguish from spondylosis but may actually be complicated by it.

Thoracic Intervertebral Disc Protrusion

I am inclined to include thoracic intervertebral disc protrusions more among the unknown than among the known facts of spondylosis. They are certainly far less common than disc protrusions at the cervical and lumbar regions, presumably for mechanical reasons. The neurologist and neurosurgeon are familiar with them as rather uncommon causes of extramedullary compression of the spinal cord. I have sometimes suspected one as the cause of an otherwise unexplained root pain, but, apart from those causing compression of the spinal cord, I have never been able to demonstrate one by myelography. This is a field which I am sure would repay research. Apart from the presence of thoracic disc protrusions sufficient to cause symptoms, I have also encountered a good many patients suffering from progressive paraplegia in association with severe thoracic spondylosis. The opportunity

Fig. 7.—Dissection of lumbar nerve-roots (L2-5). The lowest (5th) can be traced up from the lumbar sacral foramen, where it lies on the lumbar sacral disc, to where, intradurally, it passes behind the 4th lumbar disc.

for the pathological investigation of such cases rarely occurs. I have suspected that the narrowing of the intervertebral foramina by interfering with the vascular contribution which the radicular arteries make to the vasocorona of the spinal cord may contribute to an ischaemic myelopathy. Here, also, pathological research might prove rewarding.

Lumbar Disc Protrusion and Foraminal Narrowing

I have left lumbar spondylosis until last because it has been the subject of research for a much longer period than cervical spondylosis, and, until recently at least, much more has been known about it. This, however, does not mean that there are not still many important unknown factors.

It is, I think, desirable to bear in mind that the same distinction between nuclear and annular protrusions, which I discussed in connection with cervical discs, applies also to those in the lumbar region. There are certain points of difference, however, between the two. In the lumbar region acute nuclear protrusions are a much commoner cause of symptoms than at the cervical level, but it is probable that in the lumbar region pre-existing disc degeneration is a more important predisposing cause of such nuclear protrusion than it is in the neck. At the lumbar level, as at the cervical, a nuclear protrusion, if undisturbed, may provoke an osteophytic reaction from the vertebral bodies so that in the end it may be difficult to distinguish from an annular protrusion. In particular, plain radiographs may provide no clue as to whether a narrowed lumbar intervertebral disc space is the result of simple disc degeneration, annular protrusion, or nuclear protrusion.

Whereas in the neck compression of spinal nerve-roots by disc protrusion in the vertebral canal is rare compared with compression in the foramina, the reverse is generally thought to be the case at the lumbar level. Nevertheless, in the lumbar spine, exactly as in the cervical, intervertebral disc degeneration can produce damage to the spinal nerve within the foramen and in precisely the same way: first, the narrowing of the intervertebral disc narrows the corresponding foramina by bringing their edges nearer together; and, secondly, it throws an additional strain upon the articulation, so leading to osteophyte formation which in turn narrows the foramina still further. This cause of sciatic pain was hinted at by Sicard (1921) and elaborated by Putti (1927), but the subsequent discovery of intervertebral disc protrusion has led to its neglect. I believe that the symptoms of lumbar intraforaminal root compression are usually distinguishable from those of intrathecal root compression by disc protrusion. This is only to be expected on anatomical grounds, for intrathecal compression is exerted upon the posterior root of an intact ganglion whereas intraforaminal compression is exerted upon the ganglion or the spinal nerve. It should be noted that the 5th lumbar root, for example, may be compressed either by a protrusion of the 4th lumbar disc or by narrowing of the 5th lumbar foramen (fig. 7). Radiologically the 4th disc space will probably be narrowed in the first instance and the 5th in the second, with the addition, in the latter, of osteophytic invasion of the L5-S1 intervertebral foramen (fig. 8). Of course, both may be present in the same patient.

Lumbar foraminal pressure-radculitis increases in frequency with age, and is most commonly encountered in the seventh and eighth decades. It is, however, especially common in diabetics, in whom it may occur at an earlier age. It may be uniradicular or multi-radicular and unilateral or bilateral. Pain is usually less severe than in sciatica resulting from disc protrusion and is less likely to be exacerbated by coughing or sneezing. It is often, however, influenced by posture and may be worse when the patient is sitting. There

may be no pain, but only dysaesthesiae in the distribution of the dermatomes supplied by the affected root or roots. Cutaneous sensibility is often blunted over these areas. When several roots are involved there may be conspicuous muscular weakness and wasting associated with fasciculation, and diminution or loss of the knee-jerks.

* * *

Look back for a moment and recall that it is just twenty years since sciatica was first attributed to an intervertebral disc protrusion. Before that it was called sciatic neuritis and put down to various hypothetical toxins. Even at that time the same view was taken of brachial neuritis, and nothing at all was known of the protean clinical picture of spinal-cord compression by disc protrusion except for a small number of cases gathered by neurosurgeons and in which the lesion was called a chondroma. How much we have learnt since then! But how much still remains to be discovered.

I am grateful to W. R. J. Harrison for kindly providing the dissections and photographs for figs. 2 and 7.

THE DIFFERENTIAL DIAGNOSIS OF CARCINOMA OF THE BRONCHUS AND PULMONARY TUBERCULOSIS

V. URSULA LUTWYCHE
M.D. Camb., M.R.C.P.

SENIOR REGISTRAR, WILLESDEN CHEST CLINIC, LONDON

With illustrations on plate

CARCINOMA of the bronchus has, in the past, figured more often in the American than in the English medical literature. It is this fact, together with the increasing incidence of the disease, partly apparent and partly real, and the frequency with which the condition is met in routine chest-clinic practice, that has prompted this description of 7 cases. They are reported not because of any points of unusual interest but because each may be representative of many hundreds of similar cases throughout the country.

Many writers have pointed out how the early radiological changes may often resemble those produced by other conditions, making early diagnosis difficult. Burrell (1938) described the inflammatory reaction which may occur around a collapsed area of lung when a bronchus is blocked by a carcinoma. McGibbon et al. (1939) reported the results of bronchoscopic examination in 38 patients diagnosed as suffering from unresolved pneumonia; in 8 of these, bronchial carcinoma was present and the X-ray appearances were due to a secondary inflammatory reaction.

Overholt (1943) noted that, of a series of 165 patients with bronchial carcinoma, no less than 104 were at first incorrectly diagnosed; this he ascribed partly to the fact that in many cases the radiographic changes were caused by secondary effects rather than by the neoplasm itself.

Brook (1952) drew attention to the frequency with which bronchial carcinoma may present as a lung abscess; in his series of 477 cases of lung abscess, 83 (17.5%) were found to have a bronchial carcinoma as the primary cause of the condition. He stressed that this diagnosis should always be considered in every case of lung abscess, particularly in a person over the age of 45. In his series no less than 33.5% of abscesses in people over this age were due to a bronchial neoplasm.

The close similarity which may exist between the radiological appearance of a bronchial carcinoma and that of pulmonary tuberculosis is well known. In Overholt's series, 40 patients were incorrectly diagnosed as suffering from pulmonary tuberculosis and were treated in a sanatorium. Pillsbury and Wassersug (1945) described 12 similar mistakes that they had seen during the previous ten years, and Moersch and Tinney (1943) found 13 examples in their series of 448 cases.

The 7 cases described here include 5 where the correct diagnosis was not reached until it was too late to benefit the patient. In the other 2 cases the correct diagnosis was reached early in the illness, and the patients are now alive and well six and three years later respectively.

The Patients

Case 1.—A man, aged 61, a gas-meter fitter, was referred to the chest clinic in November, 1947, because he had had a recent attack of bronchitis and had lost a considerable amount of weight. The chest radiograph (fig. 1) showed bilateral apical calcification with extensive infiltration and probable cavitation in the upper part of the right lung. (The right hilar enlargement was not noted at that time.) The condition was considered to be tuberculous, although examination of ten specimens of sputum failed to reveal tubercle bacilli, and he was put to bed at home pending admission to sanatorium. His condition steadily improved with bed rest; the radiograph showed some clearing within seven weeks and he gained over 1 stone in weight in seven months. The improvement was such that his name was removed from the sanatorium list.

Eight weeks after returning to work in May, 1949, his sputum became bloodstained and he began to lose weight; at the same time he complained of hoarseness of voice and a swelling appeared at the angle of the right jaw. The left vocal cord was paralysed; and the radiograph now showed bilateral hilar enlargement. Bronchoscopy revealed considerable distortion of the carina and right main bronchus by glandular enlargement. His condition continued to deteriorate; he lost a stone in weight during the next five months, and the mass in the right posterior triangle of the neck became larger. The radiograph three weeks before death (fig. 2) showed an opacity radiating from the right hilum, consistent with a diagnosis of bronchial carcinoma. No necropsy was performed.

In spite of the fact that a carcinoma was not proved by post-mortem examination nor by histological examination of the cervical mass, it is considered that the history of this case, combined with the clinical progress, radiographs, bronchoscopic findings, and the failure to find tubercle bacilli in the sputum, leave little doubt that the whole of this patient's illness during the last three years of his life was caused by a bronchial neoplasm rather than pulmonary tuberculosis.

Case 2.—A man, aged 72, a clerk, was referred to the clinic in July, 1950, because of a febrile illness two months previously and a history of frequent attacks of bronchitis. The radiograph showed a cavitating lesion in the upper lobe of the left lung (fig. 3). This was considered to be tuberculous, though no tubercle bacilli were found in six specimens of sputum. He was put to bed at home and as a result his condition improved; he gained 5 lb. in weight during the next few months, and a radiograph after seven weeks (fig. 4) showed that the cavity was no longer visible.

Eight months after this, however, he became hoarse, his sputum was bloodstained, and he had substernal pain when lying down at night. The left vocal cord was found to be paralysed and the radiograph showed increased opacity in the left upper lobe. Bronchoscopy was not performed because it was considered that the patient would now derive no benefit from it. When seen four months later he was suffering from severe anaemia and was very dyspnoeic; he had lost 1½ stone in weight during this period. The radiograph confirmed the

clinical findings of collapse of the left lung. He died four weeks later.

In spite of the fact that in this case also the diagnosis of carcinoma was not confirmed by necropsy, it is again considered that the history, clinical progress, and radiographs, combined with the failure to demonstrate tubercle bacilli in the sputum, leave little doubt that this man, too, had a bronchial carcinoma.

Case 3.—A salesman, aged 56, was referred to a hospital outpatient department in December, 1949, on account of loss of weight and anorexia. Gastric investigations failed to find any cause for his symptoms, but a chest radiograph (fig. 5) showed some opacity in the right upper lobe, increased translucency of the lower lobe, and definite calcification of the paratracheal and hilar glands. Three specimens of sputum failed to show tubercle bacilli. In view of the calcified lesions and a negative sputum, the radiographic appearances were attributed to quiescent tuberculosis and the patient was referred back to his private doctor.

Twenty-two months later, he attended the chest clinic because of bloodstained sputum and pain in the right side of the chest; the pain had been present at intervals for eighteen months. The radiograph (fig. 6) now showed partial collapse of the right upper lobe. Bronchoscopy showed a considerable stenosis of the right upper-lobe bronchus, and biopsy proved this to be the result of a squamous-celled carcinoma. The condition was thought to be operable and the patient underwent a right pneumonectomy; but there were metastases in the mediastinal glands. The patient died from oedema of the remaining lung on the second post-operative day.

Case 4.—A window-cleaner, aged 63, was referred to the clinic in November, 1949, because of a recent attack of bronchitis and a complaint of wheeziness when lying down at night. He had had a somewhat similar pyrexial illness a year previously. The radiograph (fig. 7) at this time showed a small rounded lesion in the left upper lobe with slight enlargement of the left hilar shadow. The erythrocyte-sedimentation rate was 3 mm. in one hour (Westergren) and three specimens of sputum showed no tubercle bacilli. Bronchoscopy did not reveal any evidence of primary growth.

Twelve months later he complained of increased cough and wheeziness. The radiograph (fig. 8) now showed the lesion to be larger and a cavity was present; in addition there was more definite enlargement of the left hilum. Sputum examination still failed to show tubercle bacilli. Two months later he was admitted to hospital elsewhere for the investigation of abdominal pain, and finally underwent laparotomy, when numerous deposits of secondary growth were found in the liver and other organs. He died shortly afterwards. At necropsy a carcinomatous growth was found encircling the left upper-lobe bronchus.

Case 5.—A man, aged 51, had a routine radiograph of his chest taken when his daughter was found to be suffering from pulmonary tuberculosis. This showed a small opacity in the second right interspace, and also thickening of the interlobar septum with some opacity medially (fig. 9). There were no symptoms and these appearances were interpreted as those of an early tuberculous lesion; this opinion was substantiated two months later when the radiograph showed some clearing.

Eighteen months later he said that he had had a recent pyrexial illness with cough and that he had lost weight steadily during the past year. The radiograph (fig. 10) now showed elevation of the right diaphragm with an opacity radiating out from the right hilum. Screen examination confirmed paralysis of the right diaphragm. Bronchoscopy revealed a carcinoma of the middle-lobe orifice which biopsy proved to be of an undifferentiated squamous-celled type. Operation was considered to be contra-indicated owing to involvement of the right phrenic nerve. The patient died five months later, and there was no necropsy.

Case 6.—A fish merchant, aged 48, was referred to the clinic in May, 1947, because of cough, lassitude, pain in the right side of the chest, and loss of weight. The radiograph (fig. 11) showed an opacity in the right upper lobe with increased translucency of the lower lobe, and this was at first considered to be tuberculous, but sputum examination failed to show tubercle bacilli. He was put to bed at home while awaiting admission to hospital for further investigation, and during a period of four weeks he gained in weight.

On admission to hospital, bronchography showed a partial block of the right upper-lobe bronchus. Bronchoscopy

revealed no abnormality, but a biopsy was taken from the depth of the right upper-lobe orifice and showed a squamous-celled carcinoma to be present. A right pneumonectomy was performed and he is well and working six and a half years later.

Case 7.—A man, aged 56, a florist, first attended the clinic in October, 1947, as a contact of his wife, who had pulmonary tuberculosis; at that time his chest radiograph was normal. In October, 1950, he came again because his sputum had been bloodstained for the previous few weeks. A radiograph (fig. 12) now showed a rounded opacity in the left mid-zone, with increased translucency in the lower zone. Bronchoscopy showed no abnormality, but in view of the symptoms and radiological appearance admission to a thoracic unit for further investigation was advised. Bronchoscopy was repeated four weeks later, when a small area of the left stem bronchus was considered to be suspicious; biopsy of this proved a columnar-celled carcinoma to be present. A left pneumonectomy was performed and he is now well and working three years later.

Discussion

A study of these 7 cases, all middle-aged or elderly men, shows several points of interest. Firstly, it is very important to hesitate before accepting a diagnosis of pulmonary tuberculosis in people of this age, unless tubercle bacilli have been found in the sputum; in 5 of these 7 cases repeated examination of the sputum failed to reveal tubercle bacilli. Among others, Scatchard (1944) has stressed this point; he noted how often the radiological picture of bronchial carcinoma resembled that of pulmonary tuberculosis and urged that, if a lesion were unilateral and the sputum were negative, a diagnosis of tuberculosis should be made with great caution. He also emphasised the not infrequent occurrence of cavitation in association with a bronchial carcinoma, and he pointed out the danger that this feature alone, especially if the cavity was in an upper lobe, might lead to a mistaken diagnosis of tuberculosis. Overholt (1950), writing on the detection of cancer by means of surveys, made the same point; he remarked that, whereas abnormal shadows in the upper lobes were too often considered to be tuberculous, those in the lower lobes were often attributed to bronchiectasis or virus pneumonia.

Secondly, not every bronchial carcinoma is visible through the bronchoscope, so that the report of a normal bronchial tree does not necessarily exclude the presence of a carcinoma. In 3 of the 7 cases described above, bronchoscopy showed nothing abnormal when the examination was first made: in 1 case the true diagnosis was made four weeks later when the examination was repeated, while in another the diagnosis was made on a biopsy taken from the depths of the bronchial orifice. These 2 patients are the only survivors of the 7. Reiss et al. (1952), in a series of 70 patients with bronchial carcinoma, noted that a positive bronchoscopy (either viewing the growth direct or demonstrating neoplastic cells in the bronchial secretions) was obtained in only 63% of patients undergoing bronchoscopy. Churchill (1948) observed that bronchoscopy was of little use in aiding the diagnosis in 30–40% of cases of primary carcinoma of the lung.

It is well known that patients with a bronchial carcinoma often present with a history of recent bronchitis or other respiratory infection; and 4 of the 7 patients described here gave such a history. Jewett (1952) noted that as many as one-third of his series of 150 patients had had recurrent respiratory infections, and he pointed out how misleading was the temporary improvement which so often followed treatment with antibiotics. Another factor which may also obscure the true diagnosis is the improvement in general condition and the alleviation of symptoms when the patient is confined to bed; this improvement was considerable in 3 of the 7 cases, and in 2 of them it was accompanied by definite improvement in the radiological appearances.

Conclusions

The diagnosis of bronchial carcinoma at an early stage is seldom easy, but if the prognosis is to be improved this diagnosis should constantly be borne in mind, particularly when a middle-aged man has suspicious symptoms or an unexplained shadow in the chest. To quote Reiss et al. (1952) again, "cancer of the lung should be given primary consideration whenever one is confronted with an unexplained pulmonary lesion"; or Overholt (1950), "all patients with abnormal shadows which cannot be adequately explained on another basis should have the benefit of surgical exploration."

Physicians at chest clinics should work in close collaboration with the radiologists and surgeons; and they should discuss together all cases in which the radiological appearances are suggestive of tuberculosis but the sputum is negative, and all cases of pulmonary abscess or virus pneumonia.

Facilities for immediate bronchoscopy should be available to every chest-clinic physician; and beds should be provided in a thoracic surgical unit for the urgent admission of suspected cases.

I wish to thank Dr. C. H. C. Toussaint for his help and interest in the preparation of this paper and for permission to publish it, and Mr. A. Booker for the radiographs. I am grateful to Mr. R. Laird for the bronchoscopy reports.

With illustrations on plate

The growing interest in œsophageal disorders and their surgical treatment has revealed the need for a better understanding of the behaviour of the normal œsophagus and cardia. The following observations are based mainly on radiography and intra-œsophageal pressure measurements—two methods often employed before but not, as far as we are aware, simultaneously. We have also, in order to settle certain points, directly observed at operation the behaviour of the cardiac region.

METHODS

Pressures were measured with capacitance manometers through fine 'Polythene' tubes. Up to three tubes were used; their tips were joined and the few centimetres below the lateral recording-hole of each tube filled with mercury. The upper parts of the tubes were filled with water. In this way the spaced recording-sites could easily be located on a radiograph as the upper ends of

the mercury columns. Thin barium emulsion (specific gravity 1.2) was used as contrast medium during drinking, and 70% diodone for injection into the œsophagus through a tube. An electrical link indicated on the pressure record when the X-ray tube was energised and so provided precise timing of the radiograph. In some experiments radiographs at the rate of two a second were obtained with a Helm camera.

The subjects of the more complicated procedures were 6 normal volunteers. Much information on normal swallowing patterns was also available from records made for investigation of respiratory disorder by the method of Dornhorst and Leathart (1952).

RESULTS

Œsophageal Propulsive Wave

This wave is of characteristic form, taking about 4 seconds to complete, with peak pressure between 20 and 50 mm. Hg. It travels about 4 cm. per second with little change of form (fig. 1). There is no relaxation preceding the contraction; indeed there is usually a gentle rise of pressure, accompanying the passive expansion of the œsophagus as the contents are forced down ahead of the wave.

The propulsive wave is normally initiated by a pharyngeal swallow, but if swallows are repeated at intervals of a few seconds the propulsive wave often fails to follow; this suggests that the œsophageal muscle has a refractory period.

A propulsive wave starting in the upper œsophagus may also be initiated by the injection of air or liquid into the lower œsophagus through a fine tube.

When liquid is swallowed in a continuous series of gulps, there is no propulsive wave until the last gulp (fig. 2).

In the immediate vicinity of the cardia, the contraction becomes less forceful and lingers for up to 20 seconds (fig. 3). It is uncertain whether gastric muscle is involved in this.

Competence of the Cardia

During inspiration the intra-œsophageal pressure drops and the abdominal pressure rises. A pressure difference tending to force gastric contents into the œsophagus is set up, amounting with a moderately deep inspiration to

Fig. 1.—Pharyngeal swallows and œsophageal propulsive waves. Upper trace: pressure in pharynx. Middle and lower traces: pressures 9 and 18 cm. down œsophagus. Note that a pharyngeal swallow repeated too soon fails to initiate a propulsive wave. In this and subsequent records, time is marked at the top in seconds and pressures in mm. Hg.

Fig. 2.—As in fig. 1. During signal shown in time record at top, fluid is being drunk in a continuous series of gulps. Note propulsive wave follows only the final gulp.

some 15 mm. Hg. With an inspiratory effort against a closed glottis, much higher pressures are generated. Fig. 4 shows a difference of 80 mm. Hg maintained for 5 seconds. There is no tendency for the pressures to equalise, as must happen if there were a leak between the two regions. The normal cardia is thus extremely resistant to regurgitant flow.

Localisation of the Cardia

The opening of a recording-tube is readily moved either way through the cardia even when a considerable pressure gradient is maintained. Only a few millimetres' movement are needed for the recorded pressure to change from high to low or vice versa. A characteristic spike of pressure usually appears as the opening passes from one region to the other. It is immaterial whether a tube with a lateral or terminal opening is used (fig. 5). Similar phenomena occur with a suitably placed tube with changes in respiratory posture, presumably as the cardia is pulled over the fixed tube. With mercury-tipped tubes the recording positions are easily identified on the radiograph. From the pressure record the functional position of each tube is known at the moment of exposure, so that the radiographic position of the functional cardia can be fixed within narrow limits (fig. 6).

Resistance of the Cardia to Forward Passage

It is notable that a very flexible polythene tube is easily passed through the cardia even when it is supporting a considerable inverse pressure during deep inspiration. The cardia's resistance to forward passage of fluid was investigated in the following way:

Pressures were simultaneously recorded above and below the cardia while the region was observed on the X-ray screen. The subject rapidly drank about 250 ml. of thin barium emulsion and the first appearance of the barium in the stomach was signalled. In four experiments the screen was photographed twice a second during the critical period, each exposure

Fig. 3

Fig. 4

Fig. 3—Upper trace: pressure on oesophageal side of cardia. Middle trace: pressure on gastric side, 1.5 cm. lower down. Lower trace: gastric pressure clear of the cardia. At arrow, a mouthful of water was swallowed. The lingering pressure rise in vicinity of cardia contrasts with the steady level in stomach. Exaggerated respiratory swings in upper trace suggest that tube is lightly gripped in cardia during expiration. Fig. 4—Gastric pressures (above) and oesophageal pressures (below) during Müller's manoeuvre.

being signalled. From the data it was possible to ascertain the pressure differences required before the fluid would pass through the cardia, and the resistance to the flow once it was established. It should be emphasised that during the whole period under consideration there were no propulsive waves in the oesophagus.

The results are typified by figs. 7 and 8. The descending barium rapidly annuls the previous negative pressure gradient across the cardia and within a second or less the fluid is streaming through a widely open channel, while the pressure in the oesophagus maintains a plateau. Before this happens the gradient swings briefly positive—in fig. 7 by about 4 mm. Hg above the free-flow plateau. The maximum pressure difference reached may be considered as the "yield-pressure" of the cardia. For some seconds after a propulsive wave has reached the cardia this yield-pressure is increased (fig. 9).

The height of the pressure plateau above the level before drinking starts, and the height of the fluid column during the steady-flow period, necessarily increase with increasing depth of inspiration—i.e., with the magnitude of the inverse pressure difference which must be annulled before any forward flow can occur.

When drinking ceases a propulsive wave is normally initiated and a few seconds later it reaches the lower oesophagus, sweeping the remaining contents into the stomach.

The conclusion from these experiments is that, except for the few seconds following a propulsive wave, the normal cardia offers only trivial hindrance to forward flow: the smallness of the yield-pressure and the rapidity of yield (about 0.5 sec.) scarcely suggest a sphincteric mechanism. The height of the column of fluid apparently supported by the cardia is adequately accounted for by the inverse pressure gradient.

Rôle of the Diaphragm and other Extragastric Structures

The large inverse pressures that we have described involve contraction of the diaphragm, and it is important to determine whether this can itself occlude the oesophagus. The following observations suggest that this is not so: at the end of a thoracotomy on 3 patients with lung-disease, a finger was passed alongside the oesophagus through the diaphragmatic hiatus, while the patient recovered from the muscular relaxant; even when vigorous diaphragmatic movements were regained, no constriction of the finger by the hiatus could be felt.

The rôle of other anatomical factors was investigated as follows:

In 2 patients it was necessary to mobilise the stomach as the first stage of radical operation for carcinoma of mid-oesophagus. When this had been done and the oesophagus was freely movable in the relaxed hiatus, a tape was passed round

Fig. 5—Upper trace: pneumogram (inspiration downwards); larger excursions are normal respirations, smaller ones are inspiratory efforts with closed glottis to show position of recording sites. Middle trace: pressure at tube opening in vicinity of cardia. Lower trace: tube opening in oesophagus throughout. At signals shown in time record at top, tubes were advanced or withdrawn about 1 cm. Arrows indicate when tube crosses cardia.

the pylorus and the stomach inflated with air with a syringe. It was found that the cardia prevented the escape of air in spite of firm pressure on the body of the stomach. Air readily escaped, however, on manipulation of the cardiac region. During this procedure the stomach was not supported by the liver or other structures. The œsophagus made approximately a right angle with the slight convexity of the fundus. There was no visible groove or fold suggesting contraction of the main muscle layers.

It appears that support from adjacent structures or the maintenance of an acute angle of œsophageal entry are not necessary for cardiac competence. This is, of course, not to say that they may not assist it.

DISCUSSION

Our results show that from the point of view of function the cardia is a very localised region, extending over not more than 5 mm. This region has the characteristics of a valve—namely, very small resistance to forward passage, with the ability to resist retrograde flow in spite of large inverse pressures. The mechanism appears intrinsic to the neighbourhood of the anatomical cardia and to be independent of externally visible folding or kinking. The behaviour is unlike that of known smooth-muscle sphincters, and favours the existence of some form of flap or funnel valve. By exclusion, we have come to believe that the muscularis mucosæ, which is well developed in this region (Thomlinson 1953), pulls the lax mucosa into some valvular form. The valve must be capable of active opening for eructation of gas, which we have observed to occur with only trivial rises in gastric pressure and also for vomiting. It is well known that the cardia yields no secrets post mortem, and visual confirmation in the living subject is desirable.

There has been some controversy over the part played by the diaphragm; the increased column of barium supported in the œsophagus during inspiration has been regarded as

evidence of diaphragmatic constriction. Both our direct and indirect evidence is against this notion, which we think to be based on an ignorance of the pressure changes involved and a misconception of the respective rôles of gravity and of propulsive waves in the swallowing of liquids in the upright posture.

SUMMARY

The characteristics of normal œsophageal propulsive waves are described.

Material and Methods

Six consecutive patients with sclerodactyly were examined by radiography and their œsophageal contrac-

Fig. 9—As in fig. 7, showing effect of a recent propulsive wave on behaviour of cardia.

The normal cardia exerts little resistance to forward passage, but it has a great capacity for preventing retrograde flow. The area of the functional cardia is sharply localised. The cardia is considered to be a valve, probably formed by the action of the muscularis mucosæ on the mucosa.

Evidence is produced that the contracting diaphragm does not occlude the œsophagus.

We are indebted for technical assistance to Mr. R. W. Halls and Mr. M. G. Ventom, and to members of the physics and photographic departments of St. Thomas's Hospital.

WHILE it is well known that in symmetrical progressive scleroderma (sclerodactyly) œsophageal lesions may produce dysphagia, it is less widely recognised that in this condition a disorder of œsophageal function is frequently demonstrable when the patient is unaware of any difficulty in swallowing. We describe here the disorder and its histological basis.

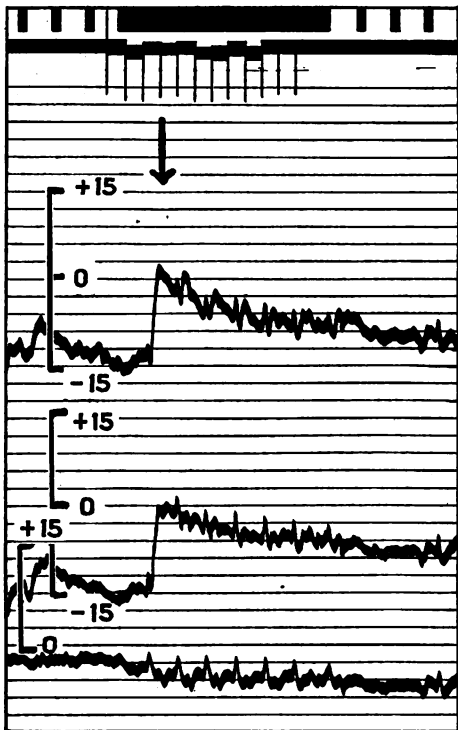

Fig. 7—Upper two traces: pressure in lower œsophagus. Lower trace: pressure in stomach. Barium drunk during long signal shown at top; films exposed at short signals shown below this. Arrow indicates timing of first film showing barium passing into stomach.

tions recorded as described by Dornhorst et al. (1954). All the patients had typical changes in the fingers; two had in addition certain features suggestive of dermatomyositis. None complained of dysphagia. Necropsy material from two further cases was available for histological study.

Results

All six patients had a definite abnormality of oesophageal function: five showed the same pattern differing only in degree; the sixth had, in addition, a stricture in the region of the cardia.

The characteristic defect was failure of the propulsive waves to continue normally into the lower half of the oesophagus. The upper half contracted with normal vigour, though usually for less than the normal time, and often with spontaneous iteration; but the contraction either failed entirely to propagate or became very feeble and incoördinate (fig. 1). The weakness of the lower oesophagus was manifest radiographically when the patient was observed swallowing in the supine, slightly head-down, position; the bolus was carried briskly to about the position of the tracheal bifurcation where its progress ceased. A further mouthful might push it on a little, but it would not enter the stomach until the patient stood up.

The microscopic appearance is of simple atrophy with minimal fibrous replacement of the main muscle-coats in the lower oesophagus—the muscularis mucosæ is unaffected. There is no sclerosis such as occurs in the dermis (fig. 2).

Fig. 1—Oesophageal pressures recorded simultaneously at different sites. The distance of each site below the cricopharyngeal sphincter is marked on the trace. The vertical bars indicate deflection produced by 50 mm. Hg. Time marked in seconds.

- (a) Normal propulsive wave for comparison. The wave, of rather less than average amplitude, is propagated into the lower oesophagus without decrement.
- (b) Failing propagation in sclerodactyly. Note adequate force, but short duration of contraction of upper oesophagus.
- (c) Iterative contraction in upper oesophagus with failure to propagate. The pressure changes in the lower oesophagus are probably entirely passive.

Discussion

Since all six unselected patients with sclerodactyly had oesophageal disorders though free from dysphagia, the association must be common. Radiographically, since there is no interference with the normal "gravity swallowing," the abnormality is easily overlooked if the patient is examined standing and a barium cream of average consistency is used. One of our patients had been reported as having a hypermotile oesophagus; measurement showed that the movements of the lower oesophagus, while quite numerous, were very feeble. Another had been described as swallowing much air but as otherwise normal: in fact there was complete paralysis of the lower oesophagus and hence no means of expelling air from it. Observation of anti-gravity swallowing is necessary for recognition of this disorder.

The microscopic appearance, radiography, and pressure measurements all point to simple muscle weakness and wasting in the lower half of the oesophagus as the essential lesion. No doubt oesophagitis, with reflux, stricture, &c., occurs as a complication in some patients.

Summary

Oesophageal disorder in sclerodactyly is common, but on radiographic examination may be overlooked unless anti-gravity swallowing is observed.

The essential disorder is weakness and wasting of the muscle of the lower oesophagus.

We are indebted to Dr. G. B. Dowling for his help in sending us patients with scleroderma.

STOKE MANDEVILLE HOSPITAL, AYLESBURY

It is now established that, given adequate treatment, the overriding factor in the prognosis of tuberculous meningitis is the stage the disease has reached at the outset of treatment. For example, in a series of 80 consecutive unselected cases treated at Oxford between December, 1949, and July, 1952, whereas the over-all mortality was 37.5%, no patient died among those 21 who were still fully conscious and rational and without focal neurological signs when their treatment was begun. Yet it is precisely in this, the most favourable, stage of the disease that diagnosis can be most difficult. As a result these favourable cases remain a small minority of the whole.

When evidence of active systemic tuberculosis is lacking, the clinical picture at this stage of the illness is simply one of mild meningeal inflammation. The abnormalities of the cerebrospinal fluid (C.S.F.) may be limited to a lymphocytic pleocytosis and some increase in the protein content, since the chloride content is seldom decreased and, not infrequently, even the glucose content is still within normal limits. The differential diagnosis is thus from virus infection of the central nervous system (especially pre- or non-paralytic poliomyelitis); from spirochætal infections, such as syphilis and leptospirosis; from brain abscess and, occasionally, tumour; and from benign lymphocytic meningitis of unknown ætiology (Cairns et al. 1950). In the absence of any distinctive clinical or pathological features differentiation may be extremely difficult; yet, if the case is really one of early tuberculous meningitis, to withhold treatment until the nature of the disease has declared itself is often to wait until too late.

Recently we have been receiving an increasing amount of help in the management of these difficult cases from the results of studies on the passage of bromide from blood to C.S.F. The opportunity to make these observations arose during the course of larger studies on the ætiology of glaucoma and of schizophrenia. The bromide test used is a modification of that devised by Walter (1929). For a critical assessment of its reliability as a means of measuring barrier permeability see Hunter et al. (1954).

Methods

Sodium bromide is used as the test substance and is given by mouth or by intravenous injection. The oral dose for adults is 1.0 g. t.d.s. for three days and for children 0.25-0.5 g. t.d.s. for three days, depending on the size of the child. The intravenous dose for adults is 8 g. and for children 2-4 g. given at a single injection. The intravenous solution is made up by dissolving 8 g. of sodium bromide in 30 ml. of sterile distilled water. After oral administration two full days is allowed for equilibrium to become established between blood and C.S.F.; after intravenous administration twenty-four hours is sufficient. The intravenous solution is moderately

irritating, causing some patients to complain of local discomfort towards the end of the injection, and care must be taken to ensure that all the solution is delivered into the vein and none allowed to escape into the surrounding tissues. The sodium bromide has had no other detectable effect on the clinical condition of the patients. The bromide is excreted so slowly that this dose has proved sufficient to maintain measurable levels in blood and C.S.F. for several weeks.

When equilibrium has been established, samples of venous blood and of C.S.F. are collected into dry and

SERUM/C.S.F.-BROMIDE RATIOS IN "NORMAL" CONTROLS

Condition	No. of cases	Bromide ratio	
		Range	Mean
Psychosis	13	2.20-3.39	2.68
Glaucoma	6	1.95-2.97	2.52
Tuberculosis without meningitis ..	5	2.03-3.05	2.53
Total	24	1.95-3.39	2.61

chemically clean test-tubes. Venous blood 5 ml. and C.S.F. 3 ml. are sufficient to allow the estimations to be done in duplicate. The clotted blood is centrifuged and the bromide contents of the serum and C.S.F. are estimated. The results are expressed as the ratio of the serum-bromide level to the C.S.F.-bromide level (serum/C.S.F. bromide). This we call the bromide ratio.

All the ratios given here are based on lumbar C.S.F. Since the bromide content of cisternal and ventricular fluids is lower than that of lumbar C.S.F., ratios based on those fluids are not comparable with ratios based on lumbar C.S.F.

All the bromide estimations were made by an iodometric titration method (Hunter 1953).

Results

"NORMAL" CONTROLS

By this method of determination we find that, in the absence of detectable organic disease of the central nervous system, serum contains two or three times as much bromide as does C.S.F.—in other words, the bromide ratio is 2-3. These results (see table) were obtained from cases of various kinds of psychosis, from cases of glaucoma, and from cases of tuberculosis without evidence of meningitis.

These ratios are significantly lower than those reported by Walter (1929). This discrepancy is undoubtedly due to the different method used for the bromide estimations. Walter and his immediate followers used the gold-chloride method for their estimations. The bromide levels of several samples of blood and C.S.F. have now been estimated both by the gold-chloride and by the iodometric titration methods. Whereas the results obtained by the two methods in C.S.F. were in close agreement, some substance other than bromide was present in blood that reacted with the gold chloride to give the same brown colour. The serum-bromide levels, and consequently the bromide ratios, estimated by the gold-chloride method are too high (see Hunter et al. 1954).

We have now estimated the bromide ratio in several neurological disorders, especially tuberculous meningitis, non-purulent meningitis other than tuberculous meningitis, and during intrathecal tuberculin reactions. A full report of our findings is in preparation, but certain points of practical importance are briefly discussed here.

DURING INTRATHECAL TUBERCULIN REACTION

By the intrathecal tuberculin reaction is meant that wave of meningitis which follows the introduction of tuberculin into the C.S.F. of a Mantoux-positive person

* Based on communications given to the Association of British Neurologists and the Association of Clinical Pathologists.

† Working with a grant from the Medical Research Council.

with normal meninges and without active tuberculosis. This meningitis, which undoubtedly reflects a true specific antibody-antigen reaction, affects both the cellular and protein content of the c.s.f. and is, when fully developed, diphasic (Swithinbank et al. 1953). The reaction has a dramatic effect on the passage of bromide from blood to c.s.f. During the first phase of the reaction the serum/c.s.f.-bromide ratio falls to unity; in other words, the blood-c.s.f. barrier to bromide is abolished. The ratio remains at or below unity throughout the second phase of the reaction and then slowly begins to climb, but it is many weeks before the barrier is completely re-established. That the ratio is a reliable indicator of the permeability of the blood-c.s.f. barrier to bromide is shown by the fact that it is independent of the absolute amounts of bromide present in blood and c.s.f. (fig. 1).

The rise of the c.s.f.-bromide level is often, but by no means invariably, associated with a rise of the c.s.f.-protein level. At the beginning of the reaction the serum/c.s.f.-bromide ratio falls as the c.s.f.-protein level rises; but, as the reaction develops, the two tend to become dissociated, until finally the c.s.f.-protein level returns to normal before the bromide ratio. A dissociation between the c.s.f.-protein level

Fig. 1.—Intrathecal tuberculin reaction in a person with normal meninges.

Note (1) steady fall in serum-bromide level until 52nd day, when another three-day oral "course" (total 9.0 g. of sodium bromide) was given; (2) rapid rise in c.s.f.-bromide level after intrathecal injection of tuberculin on day 1; (3) abrupt fall of bromide ratio after injection of tuberculin, and its steady recovery, still incomplete after 102 days (increase in serum-bromide and c.s.f.-bromide levels between days 50 and 60 had no effect on ratio); (4) diphasic rise in the cell-counts and protein content of c.s.f. (during first phase serum/c.s.f.-bromide ratio falls sharply to 1 and only begins to climb as the second phase subsides).

and a disturbance of the bromide ratio has been seen in other neurological conditions. The one condition we have so far found in which a low bromide ratio has invariably been associated with a high c.s.f.-protein level is spinal block. Whether the block has been due to spinal-cord tumour or to tuberculous meningitis, the ratio for the fluid below the block has always been about 1.

Fig. 2.—Bromide-ratio distributions in 33 cases of early proved tuberculous meningitis and in 33 cases of non-tuberculous "non-purulent" meningitis. For further explanation see text.

TUBERCULOUS MENINGITIS

Active tuberculous meningitis appears to have the same effect on the blood-c.s.f. barrier as does the intrathecal tuberculin reaction. In our experience it has been the rule for the ratio to be profoundly depressed but to return to normal when the infection is brought under control. Even when intrathecal tuberculin was not used in treatment, values of 1 or less were common.

Moreover, this fall in the ratio appears to happen early in the illness.

For example, two young women were admitted to hospital at about the same time, both with miliary tuberculosis. As soon as the diagnosis was established radiographically, a routine lumbar puncture was done in each case. In the first the lumbar c.s.f. contained 2 cells per c.mm. and protein 35 mg. per 100 ml. The bromide ratio was 2.18—i.e., within normal limits. The patient made a straightforward recovery without ever developing any signs or symptoms of meningitis.

In the second case the lumbar c.s.f. contained 10 cells per c.mm. and protein 120 mg. per 100 ml., but the bromide ratio was only 0.99. The patient was treated for tuberculous meningitis, and the diagnosis was later confirmed when *Mycobacterium tuberculosis* was cultured from an early specimen of c.s.f. Shortly after conclusion of the intrathecal therapy the ratio had risen to 2.39; and at her last follow-up, seventeen months after the beginning of her illness, it was 2.97.

The results obtained in 33 cases of tuberculous meningitis are shown in fig. 2. The diagnosis was confirmed in all the cases by the isolation of *M. tuberculosis* from the c.s.f. This figure is restricted to estimations of the bromide ratio made during the first month of treatment, since this is a period for which it is certainly justifiable to treat suspected but unproved cases of tuberculous meningitis. None of these patients had received any intrathecal tuberculin before the bromide test, nor did any of them show evidence of a spinal block. These are, of course, necessary conditions for comparison, since the intrathecal injection of tuberculin can lower the ratio to 1 or less even in people with normal meninges, and the ratio is always low for the fluid below a spinal block.

OTHER VARIETIES OF NON-PURULENT MENINGITIS

In other varieties of non-purulent meningitis a fall in the bromide ratio comparable with that found in tubercu-

Fig. 3—Serum/C.S.F.-bromide ratio plotted against amount of protein and cells in C.S.F. in tuberculous and non-tuberculous cases of meningitis. Findings in tuberculous cases are shown by circles and in non-tuberculous by crosses. For further explanation see text.

lous meningitis has proved exceptional. Even though the changes in the number of cells and the amount of protein in the C.S.F. were about the same as those in tuberculous meningitis, the blood-C.S.F. barrier to bromide was, on the whole, remarkably well maintained. This finding suggested that the bromide test might be used as an aid to the diagnosis of tuberculous meningitis. Accordingly the ratio was estimated in 33 cases of non-purulent meningitis that was not tuberculous. The composition of this group is shown in the following list, which includes many of those conditions from which the differentiation of early tuberculous meningitis can be most troublesome:

Diagnosis	No. of cases
Paralytic poliomyelitis	9
Choreolymphocytic meningitis (mouse-borne)	1
Neurosyphilis	2
Leptospirosis	1
Cerebral abscess	1
Intracranial tumour	1
"Lymphocytic meningitis" * of unknown aetiology	18
Total	33

* Includes probable cases of non-paralytic poliomyelitis.

The ratio distributions for the cases in these two groups are shown in fig. 2. In the great majority of the tuberculous cases the ratio was between 0.7 and 1.29, and in only 3 of the 33 was it higher than 1.6. The ratio distribution for the non-tuberculous cases shows a flatter peak, as might be expected in a group of mixed aetiology. But, by contrast with the tuberculous cases, in only 2 of the 33 was the ratio lower than 1.6. Thus, with 1.6 as the critical level, in 5 cases out of 66 the ratio fell out of place, giving an error of about 7%.

This difference in the bromide ratios of the two groups is largely independent of any differences in the amounts of protein and cells in the fluids (fig. 3). Except for a few tuberculous cases in which a very high protein content was invariably associated with a low ratio, the disturbance in both cells and protein was about the same in both groups of cases, and in the tuberculous cases a trivial increase of protein proved quite compatible with a low bromide ratio.

EFFECT OF INTRATHECAL CHEMOTHERAPY

Several of the patients in the non-tuberculous group were originally suspected of being tuberculous and were receiving daily intrathecal injections of streptomycin,

or of streptomycin and isoniazid, when the bromide ratio was estimated. In spite of this the ratios were not obviously depressed. We therefore conclude that this form of intrathecal medication has no significant effect on the blood-C.S.F. barrier to bromide.

Discussion

There is already a considerable amount of circumstantial evidence that the changes in the C.S.F. in tuberculous meningitis are the expression of spontaneous intrathecal tuberculin reactions—i.e., of a hypersensitivity or antibody-antigen response (Cairns and Smith 1952). The finding that the disturbance of the bromide ratio is identical in tuberculous meningitis and in the experimental intrathecal tuberculin reaction strongly supports this hypothesis. It also suggests that some mechanism other than a hypersensitivity effect must be at work in the production of the C.S.F. changes in many of the other varieties of non-purulent meningitis.

From the point of view of diagnosis we do not for one moment suggest that a low bromide ratio is pathognomonic of tuberculous meningitis. Nor must the result of the bromide test be considered in isolation from the other findings, clinical and pathological. But in doubtful cases where the picture as a whole is compatible with the diagnosis of tuberculous meningitis the finding of a low bromide ratio is strong reason for beginning treatment without further delay.

Summary

The diagnosis of tuberculous meningitis in its early and most favourable stage may be extremely difficult.

The bromide test for permeability of the blood-C.S.F. barrier is described, and evidence is presented that the barrier to bromide is more frequently and more seriously impaired in tuberculous meningitis than in other varieties of meningitis with comparable changes in the C.S.F.

The bromide test may therefore prove helpful in the early diagnosis of tuberculous meningitis.

AMINO-ACIDURIA IN MARCH HÆMOGLOBINURIA

M.B. Manc.

CAPTAIN R.A.M.C.; JUNIOR SPECIALIST IN PATHOLOGY

SHORNCLIFFE MILITARY HOSPITAL

MARCH hæmoglobinuria is an uncommon and apparently harmless transient disturbance after exercise in the upright posture. Most usually it affects young men, but Gilligan and Altschule (1950) have described the syndrome in a young woman and consider that it is commoner in females than is usually supposed. Because this disorder is benign and transient, our knowledge of its pathology is slight, although its clinical aspects have been fully described (Witts 1936, Gilligan and Blumgart 1941, Gilligan et al. 1941, 1943, Palmer and Mitchell 1943, Hobbs 1944, Kurz 1948, Lubran and Sakula 1949, Whitby and Britten 1950, Plumb 1951).

The colour of the urine is startling enough to bring the patient to his doctor. It is classically described as being

of a port-wine colour, but the patient's description of it as resembling black blood is equally apt. Associated symptoms are usually absent, though there may be slight aching in the loins. The hæmoglobinuria is directly related to exercise in the upright posture; swimming or cycling never result in the syndrome. Gilligan and Blumgart (1941) have strikingly demonstrated the influence of posture by showing the inhibitory effect of increasing kyphosis on the degree of intravascular hæmolytic. Usually the disturbance occurs after an unaccustomed degree of exercise—many cases have been described in young recruits to the Armed Forces—but the exercise threshold tends to be constant for each individual. Summation may be apparent, as in a patient we saw who only had the syndrome if he played football two days in succession. Discoloration is maximal immediately after exercise, and decreasing amounts of hæmoglobin are found in urine passed during the next few hours. By the time the patient reaches hospital his urine is usually quite clear, and the diagnosis has to be made from the history, with laboratory tests to exclude other causes of hæmoglobinuria and hæmaturia. After a period varying from a few months to several years the attacks disappear spontaneously, and these do not recur in later life.

Two main factors seem to produce this disorder:

1. Increased hæmolytic. The plasma-hæmoglobin is normal at rest but after exercise rises to abnormally high values; its level increases with the degree of the exertion and falls as soon as the exercise is stopped (Gilligan and Blumgart 1941, Gilligan et al. 1943).

2. Renal tubular defect. By correlating the time of onset of hæmoglobinuria with the plasma-hæmoglobin values, it has been found that the renal threshold for hæmoglobin in these patients is much reduced. This abnormality is probably not related to the exercise since a similar threshold is found during rest (Gilligan and Blumgart 1941, Gilligan et al. 1941). Gilligan et al. (1941) have shown in normal subjects that, once this peak is exceeded, excretion of hæmoglobin will continue at levels as low as 50% of the normal threshold.

Material

While investigating a patient with a history of march hæmoglobinuria, we observed that he was a natural excretor of β -amino-isobutyric acid. On the basis of this case and the known renal tubular abnormality in patients with march hæmoglobinuria, we decided to examine for abnormal amino-acid excretion the urines of as many patients as possible who had had this complaint. The Army authorities kindly collected for us the case-notes of 24 patients who had been in hospital with symptoms suggestive of the syndrome during the past seven years. Owing to the nature of the disorder, hæmoglobinuria was seldom observed in hospital, and "probable" cases of march hæmoglobinuria were selected by the following criteria:

1. The patient must be a young man who gave a history of passing dark red urine directly related to exercise in the upright posture, with absent or only slight associated symptoms.

2. Absence of red blood-cells on microscopical examination of the urine was likewise essential.

3. At least one of the following investigations must have yielded supporting evidence: (a) oxyhæmoglobin found on spectroscopic examination of the urine with absence of red blood-cells on microscopy; (b) negative serological examination of the blood; or (c) negative radiographic and bacteriological examination of the urinary tract.

Of the 24 cases, 15 appeared from their notes to be "probables" and we were able to obtain early morning specimens of urine from 11 of these, making 12 in all with our original case.

Methods

Samples of early morning specimens of urine were obtained from the 12 patients and stored in a refrigerator with a crystal of thymol as preservative. Volumes of urine containing 0.015 mg. of creatinine were spotted on

RESULTS OF TESTS ON EARLY MORNING SPECIMENS OF URINE FROM 12 PATIENTS WHO HAD MARCH HÆMOGLOBINURIA IN THE PREVIOUS SEVEN YEARS. THE RESULTS FOR CHEMICAL ANALYSIS OF CYSTINE ARE GRADED FROM 0 TO 4 ARBITRARY UNITS

Case no.	Cystine		B.A.I.B.	Generalised amino-aciduria
	Chem.	Chromat.		
1	3	++	+	+
2	4	++	+	+
3	2	+	+	0
4	1	+	+	0
5	2	+	+	0
6	2	++	+	0
7	3	++	+	0

12	2	+	0	0

to 20-cm. squares of Whatman no. 1 filter-paper and run as two-dimensional chromatograms, using phenol-water and collidine-lutidine-water as solvents.

Cystine was demonstrated chromatographically by oxidation with 30% (100 vol.) H_2O_2 and 0.1% ammonium molybdate, and chemically by the cyanide-nitroprusside test of Brand et al. (1930). A rough quantitative estimation was attempted by this latter test, grading the intensity of colour response in 0-4 arbitrary units. β -amino-isobutyric acid was identified by the following procedures:

1. β -amino-isobutyric acid (kindly presented to us by Mr. R. G. Westall) occupied a similar position on the chromatogram and also reinforced the unknown spot when both were put up together.

2. Hydrolysis with concentrated hydrochloric acid at 100°C for twenty-four hours did not change the chromatographic properties of the substance.

3. Similarly, it was not affected by oxidation with 30% (100 vol.) H_2O_2 and 0.1% ammonium molybdate.

4. "Copper runs" were done by the method of Crumpler and Dent (1949), these leaving the unknown spots unchanged.

Results

The results of the urinary analyses are shown in the accompanying table. Cystine was excreted in excess in every case. β -amino-isobutyric acid (B.A.I.B.) was present in 11 of the 12 cases, although in 2 of these the quantity was small. In 2 cases there was pronounced general amino-aciduria, including B.A.I.B.

As far as our methods would allow of quantitative assessment, the results suggested a correlation between the amounts of cystine excreted and the presence or absence of other amino-acids in the urine. Thus in both the cases with generalised amino-aciduria there was evidence of a larger excretion of cystine in the urine than in most of the other cases. Conversely only comparatively small amounts of cystine, although larger than normal, were present in the urines of the 3 patients who showed either an absence or only traces of B.A.I.B.

Discussion

Gilligan et al. (1943), observed increased hæmolytic in 18 out of 26 marathon runners. Whereas the accepted level for normal persons at rest is less than 6 mg. hæmoglobin per 100 ml. plasma, values of 15-44 mg. per 100 ml. plasma were found in their series; and 3 of the runners had actual hæmoglobinuria. Patients with march hæmoglobinuria have a tendency to abnormal intravascular hæmolytic after relatively moderate exercise, although there would appear to be no clear-cut distinction between normal and abnormal (Witts 1936, Hobbs 1944, Lubran and Sakula 1949, Plumb 1951).

For hæmoglobin to appear in the urine, hæmolytic must occur to such an extent that the plasma-hæmoglobin level is greater than the renal threshold for this substance. Conceivably this could occur with the normal renal threshold of over 135 mg. per 100 ml. plasma (although

such a state has not, to our knowledge, been described). Obviously hæmoglobinuria would be more likely in the presence of a low renal threshold; and indeed hæmoglobin has been found in the urine with plasma values of less than 100 mg. per 100 ml. (Gilligan and Blumgart 1941, Gilligan et al. 1943, Palmer and Mitchell 1943, Hobbs 1944, Lubran and Sakula 1949, Gilligan and Altschule 1950, Plumb 1951).

Many workers' estimates of the renal threshold for hæmoglobin were based on plasma samples taken from their patients after the exercise had been completed. These figures were thus, perhaps, abnormally low; for Gilligan et al. (1941) have shown by intravenous injection of hæmoglobin that, once the renal threshold has been exceeded, hæmoglobin will continue to be excreted at much lower plasma levels. In the resting patient Gilligan et al. demonstrated an initial renal threshold of 30-75 mg. per 100 ml. plasma in patients with march hæmoglobinuria, but their experimental method precluded any estimate of the specific effect of exercise.

This low but variable renal threshold to hæmoglobin suggests that these patients have a renal tubular defect of differing severity. Our experimental findings indicate that this same defect involves tubular reabsorption of amino-acids. The degree of amino-aciduria cannot be correlated with the clinical severity of the syndrome, since the hæmoglobinuria depends not only on the renal threshold but also on the amount of intravascular hæmolysis.

In our cases increased urinary excretion of cystine was a constant finding. The two with the highest urinary cystine level showed a chromatographic pattern consistent with heterozygous cystinuria (Harris and Warren 1953). It would be interesting to assess the renal threshold to hæmoglobin in other conditions associated with an excessive cystine excretion, such as the Fanconi syndrome, Wilson's disease, and homozygous cystinuria (Dent 1947, Uzman and Denny-Brown 1948, Cooper et al. 1950, Dent and Rose 1951). Urinary B.A.I.B. is almost as constantly associated with march hæmoglobinuria as is excess urinary cystine. In a large majority of our cases B.A.I.B. was present in the urine, although it is found chromatographically in only about 10% of the general population (Harris 1953). We suggest that the reabsorption of cystine, B.A.I.B., and hæmoglobin takes place in the same or adjacent sections of the renal tubule and that the low renal threshold in march hæmoglobinuria is a non-specific tubular defect.

Summary

March hæmoglobinuria is due to an association of two abnormalities: (1) increased intravascular hæmolysis on exertion in the upright posture; and (2) lowered renal threshold to hæmoglobin. This renal tubular defect also manifests itself in amino-aciduria.

It is suggested that cystine, β -amino-isobutyric acid, and hæmoglobin are reabsorbed in the same or adjacent sections of the renal tubule, and that the low renal threshold in march hæmoglobinuria is a non-specific tubular defect.

We should like to thank Dr. Harry Harris for his advice on the classification of the cystinurias. This work would not have been possible without the willing coöperation of the Army Medical Statistics Department and various regimental record offices. We are grateful to the A.D.M.S., Home Counties District, for permission to publish this paper.

From Ham Green Hospital, Bristol, and the Bristol Aeroplane Company

IN this country we still largely depend on the Both respirators donated to the nation by Lord Nuffield. Possibly we would have been in a much worse case since 1947 but for the extraordinary foresight represented by these gifts, though up till then the supply sufficed so well that advances in respirator design may have been delayed. Despite any criticism, the Both machine has given invaluable service; and the Ministry of Health (1953) has advocated modification of this apparatus rather than the introduction of a new respirator.

In April, 1953, a review of resources for artificial respiration in this hospital showed that we were almost wholly dependent on Both machines already much depreciated by time and use; and we had no means of positive-pressure respiration. As an immediate priority the Clevedon respirator was developed (Macrae et al. 1953); and in August, 1953, work began on a new type of cabin respirator to improve on the Both machine.

Design

Advice was sought extensively from nurses much experienced in the use of respirators and from intelligent ex-patients. Nurses emphasised the sheer physical work involved in using telescopic machines, the space occupied by such machines when extended, the worry of working against time when the apparatus is opened, the relative immobility of the machine, and the almost complete uselessness of the hand ports lavishly provided on some respirators. Patients' criticisms applied to the appearances of the tank, the inflexibility of the neck seal, the suffocating sensation each time the tank was opened, and the equal discomfort of lung inflation through a face-mask.

The 'Bristol' respirator is shown in figs. 1-4. As will be seen (fig. 1), when ready for use this looks like a bed.

RESPIRATOR CABIN

The cabin has a rectangular box-type base, and it is fitted with a hinged and detachable dome at the head end and a long cover hinged at the foot end. This cover, which has six 'Perspex' windows giving clear vision to the whole of the inside, is balanced by means of a swinging weight and is secured in position by quick-acting lever clamps, one on each side.

The end panel is split longitudinally, the lower half being the head end of the box base while the upper half is part of a separately detachable component (fig. 3). This combination of end-pieces contains the neck seal, which is of reinforced sponge-rubber; if necessary, this can be replaced with an inflatable seal. The upper

component is secured to the main box with quick-acting clamps, one on each side. The hand openings or doors (one either side) are fitted with rubber seals, to reduce air leakage when the hand is inserted, and with rubber gaskets and quick-acting clamps.

The hinged perspex dome connected to the end panel can be lowered over a patient's head and fastened by two lever clamps (fig. 4). When not in use the dome is held open by a hinged fork, or it may be removed by withdrawing the two hinge-pins.

The head rest (fig. 1) has a sponge-rubber pillow: it is circular except for a cut-away to provide extra clearance if necessary; it has vertical and sliding adjustments and can be rotated; it permits bronchoscopy.

A box, fitted externally to the foot of the cabin, has a sliding panel on which the air-duct

Fig. 2—The respirator in use.

from the pumping unit is fixed. Sliding this panel sideways selects either a duct to give vacuum to the cabin or a duct to give pressure to the perspex dome through a channel built into the cabin floor. The box is also fitted with valves to control the air-pressures supplied to either the cabin or the dome. An additional valve in the dome permits a controlled flow of air for ventilation and prevents condensation.

The cabin is fitted with two pressure-gauges, one showing vacuum inside, and the other connected by a pipe to record positive pressure in the dome when that is in use. These gauges are identical; the scales (black for positive and red for negative pressure) indicate pressures of 0–35 cm. of water, positive or negative.

A drawer is fitted under the cabin on the undercarriage frame.

The respirator, supported on four castors fitted with foot-brakes, is easily moved by one nurse.

The dimensions are as follows:

Inside length of cabin	5 ft. 10 in.
Maximum inside breadth of cabin	2 ft. 5 in.
Diameter of dome	1 ft. 10 in.
Minimum height of bed from floor	2 ft. 8 in.
Maximum over-all width	2 ft. 10 $\frac{1}{2}$ in.

Adjustment of Cabin

The cabin is set in position on an undercarriage by means of three screw-jacks, two at the head and one towards the foot, mounted on a tubular hinged frame. The jacks are independent and attached to the underside of the cabin by universal joints and ballbearings; that at the foot is fixed to a sliding plate. The greatest "upward" adjustment is 10° at the head and 23° at the foot end. Either side at the head can be tilted 15° sideways. Intermediate positions can be obtained within these maxima.

The mattress frame is mounted at the head on two screw-jacks connected together by a roller-chain.

Fig. 1—The respirator ready for a patient.

This provides a vertical movement of 5 in. and gives close control of the patient to suit neck-seal requirements. A foot rest, adjustable along the length of the mattress, is included (fig. 1).

THE PUMP UNIT

The pump unit is separate from the cabinet and readily detachable (figs. 2 and 5). It consists of a $\frac{1}{2}$ H.P. electric motor running at 1450 r.p.m., driving through a variable-speed pulley (expanding type), range 3 to 1, and a worm gearbox of 25 to 1. This gives final speeds of approximately 30–10 r.p.m.; variation between these limits is made by turning a small wheel to adjust the motor on slide rails.

The gearbox output shaft is fitted with a gear-wheel meshing into a similar wheel mounted on its own bearing shaft. These gears are mounted eccentrically, thereby giving a changing velocity ratio with an expiration to inspiration value of 4 to 3.

The pump itself is of the bellows type, consisting of two end-boards connected by leather. The top board of the bellows is supported on a base frame by three vertical tubes which also act as roller-

Fig. 4—The perspex dome in use.

guides. The top board is fitted with adjustable positive and negative pressure relief-valves and a detachable coupling for the air duct (2 $\frac{1}{2}$ -in. flexible hose). The bottom board has a fitting to take a connecting-rod which is also attached to a lever on a layshaft to the side of the unit. On this shaft is another lever carrying a connecting rod attached to a pin in the face of the lower gear-wheel, thus imparting a reciprocating motion to the bellows.

The two levers on the layshaft are connected together by means of a dog coupling, sliding on a serrated sleeve whereby the motor can be disconnected and the pump operated manually by a lever positioned at one end of the shaft. This hand lever is normally within the casing which surrounds the unit, but can readily be withdrawn to operating position. The dog coupling is moved as required by a hand lever. The complete pump unit is enclosed in a casing and is mounted on four easily moving castors.

The Respirator in Use

The respirator was first used on Dec. 26, 1953. It has been used in five cases of respiratory paralysis, due to poliomyelitis, in adults. One patient, a State-registered nurse, did not recognise the apparatus as a respirator when she saw it ready for her reception. This patient, who was in the respirator for fifteen days, has nothing but praise for it, particularly on account of the comfort and the continuity of breathing provided by the positive-pressure dome.

The dome, which has been needed in three cases, has been a happy revelation to nurses accustomed to older types of respirator. It has been used for as long as forty-five minutes at a time—one patient fell asleep in it—and no ill effects have been reported or observed. Nursing has been unhurried, unworried, and accomplished in less time than the necessarily staccato performance with older types of respirator. One nurse can do all nursing tasks alone, except for major changes

of position; and these are quickly completed by two nurses. It is helpful—and comforting—to be able to see the whole patient in the respirator.

Adjustments have proved easy; and the application of various tilts has proved useful. Though the neck seal is firm, it bears no pressure from weight or angulation of the neck when the positions of the bed and of the head rest are suitably adjusted. The colour of patients has remained good, and they have slept well.

As a result of experience, we believe that this respirator would be further improved by providing hydraulic jacks instead of screw-jacks in the tilting mechanism, a quieter expanding pulley in the pump unit, an alarm

Fig. 5—The pump unit.

system (already on order), and inflatable neck seals. So far the machine has proved reliable.

The production of this respirator has been a happy experience of coöperation. We thank the Bristol Aeroplane Company and the South Western Regional Hospital Board for great interest and encouragement in this work; and are grateful for advice and unfailing help from Sister S. Williams, of Ham Green Hospital, and many others.

Ministry of Health (1953) Circular R.H.B.(53)56.

“... we seem farther from the goal of ‘social sciences’ than ever we were. And the chief reason is not that, like the natural scientists, we have run into up-to-date complex inconsistencies and non-causal relationships in the phenomena we study, but that we have not yet reached the first stage of agreed classifications, nor agreed on definition and determination of the phenomena social scientists are supposed to study. ... The gulf between the psychologists, engaged with individuals, and the social psychologists is notorious; indeed, social psychology in Britain can scarcely be said to have advanced for a generation, in spite of the advances in psychology as a whole. What exactly are these social scientists studying; along what lines are their studies carrying them; towards what goals? The natural scientists today can still broadly answer such questions. The social scientists cannot.”

A NEW CABINET RESPIRATOR

J. F. GALPINE

M.D. Leeds, M.R.C.P.E., D.P.H.

CONSULTANT IN INFECTIOUS DISEASES, COVENTRY,
WARWICKSHIRE

In June, 1952, the Birmingham Regional Hospital Board appointed a committee on which Captain G. T. Smith-Clarke, of Coventry, was invited to sit as consulting engineer to find means of improving the existing Both respirator. A performance specification issued by the breathing-machines committee of the Ministry of Health was used as a basis for discussion, and Captain Smith-Clarke agreed to modify one Both respirator to see how far the specification could be met. Eventually five Both respirators held by the Hospital Management Committee in Coventry were modified up to what was later known as stage 1 (Smith 1953a). The experience gained in the first stage revealed that more could be done to provide comfort for the patient and to reduce difficulties in nursing. The stage-2 modification followed, and this included a “split head” (Smith 1953b).

Success with the split head suggested to Captain Smith-Clarke that further advantage would accrue if the whole cabinet could be split so as to open alligator-fashion from the head end; means for withdrawing the bed would then become unnecessary, and the patient would be immediately accessible in the most complete way. To do this demanded an entirely new cabinet, and in the autumn of 1952 a scale model was made of a split cabinet respirator to show the feasibility of this principle. At this stage local interest awakened, and various donors made contributions towards the cost of developing a prototype model which could be put into service in the Coventry group of hospitals. In addition during the coronation procession in Coventry about £800 was collected in the streets; this was added to what became known as the Coventry Iron Lung Fund. Finance being thus assured, Captain Smith-Clarke arranged for a full-size prototype complete with a newly

Fig. 1—Respirator (open) and pumping unit.

designed pumping unit (figs. 1-3) to be made to his instructions.

The Respirator

The lifting section is moulded in one piece from fibre glass; the bed portion and the stand are made of aluminium alloy and steel.

The shape of the cabinet is such that the patient's head projects at the apex of an obtuse angle, thus ensuring that in both the prone and the supine positions the head-board slopes away from the patient's chin.

The two half-collars are held in position by clamping plates which are readily removable.

Means are provided externally to centre the patient's neck in the collar by raising the entire bed rather than merely a section towards the head-end. The double control fitted for this purpose can be used to give a small amount of lateral tilt to the bed if desirable.

A fully adjustable pillow support is provided, and by the removal of two pins the complete support can be slung down to allow hyperextension of the neck for bronchoscopy.

The top of the cabinet is hinged at the foot and can easily be opened and closed by a nurse, because it is counterbalanced by two arms containing compression springs. In the unlikely event of a spring breaking, the compression action would only allow a small drop, and in no foreseeable circumstances could the top fall unchecked. Guides are provided on the base to facilitate accurate reseating on closure.

The foot rest is as in the modified Both respirator.

The respirator can be tilted on a pivot from 10° head-up to about 25° head-down. The pivot is so placed that, on tilting head-down, the head of the patient remains in a convenient position for nursing. The mechanism for tilting is purely mechanical and positive, and is so arranged that a nurse can easily operate it.

A continuous seal on one plane is used, and the top is secured with two large quick-acting clips near the head end.

Hand ports are provided on each side, but no so called bedpan opening has been fitted, because the cabinet is so easy to open and close. Future models will, however,

Fig 3—Respirator (closed) and pumping unit.

have such an opening in the position found very useful in this hospital for introducing nursing equipment usually other than bedpans—e.g., additional blankets, sand-bags, catheters, kidney dishes, woollen pads—and for giving hypodermic injections. A full view of the patient is provided by two rows of 'Perspex' panels.

A compound pressure gauge indicating negative and positive pressure is mounted centrally on the top of the cabinet; it can be rotated so as to be visible from any desired position.

A negative-pressure valve, giving fine adjustment with positive locking, is fitted on the foot end.

An automatic alarm indicates within less than 30 seconds, by a red light and a bell, any fall of pressure below the desired point; this is the same device that was fitted on the modified Both respirator.

The mattress is 70 in. long, 28 in. wide at the head end, and 18 in. wide at the foot end. The over-all external dimensions of the respirator are 8 ft. 1½ in. long, 2 ft. 7 in. wide, 4 ft. high with top closed, and 7 ft. 6 in. high with top fully open.

Pumping Unit

Though it has many of the features of a normal pumping unit, this model has, instead of the conventional connecting rod, a sliding cross-head forming part of a lever pivoted to the base plate. This is so arranged as to provide a better breathing pattern than can be obtained with a connecting rod. The negative pressure, is smoothly built up over an angle of about 170°, leaving 190° available for expiration. The use of the lever obviates the necessity for any other guiding mechanism on the bottom end of the bellows, thus abolishing the noise often arising at this point.

The hand-pumping-gear is on the general lines of the system used in the fully modified Both respirator but has been made entirely fool-proof. Instead of removing a pin to allow of hand-pumping and replacing it when power is again available, the pin in the new unit remains always in place, being partially withdrawn and turned through 90°

Fig. 2—Pumping unit and respirator (closed).

to look it in the withdrawn position when hand-pumping is required. At the end of hand operation power-pumping can be re-started merely by reversing the 90° turn of the pin, when it will automatically spring into engagement as its socket on the moving central spindle comes into position. It is completely impossible to do anything wrong with this hand-pumping mechanism.

Positive pressure is controlled by a non-return disc valve located on the pump unit. Smooth adjustment without fear of accidental alteration is given by a screw with knurled head and a knurled locking nut.

The whole of the pumping unit has been designed on exceptionally strong lines to allow of long periods of use with minimal servicing. With positive and negative controls both at maximal setting the pressures attained are +19 and -25 cm. water. A perforated guard, which can be opened and folded back, gives access to the motor and bellows without having to remove the pressure hose. The prototype pump has a continuously variable gear giving speeds of about 12-25 cycles a minute, but it is believed that for general purposes a five-step pulley with a very easy method of changing the belt will be preferable. A five-step pulley will probably be provided on the standard respirator with the continuously variable gear available as an extra if required.

MAJOR, R.A.M.C.

T. PHILLIPS

M.B. Belf.

LIEUTENANT, R.A.M.C.

From the Medical Division, Tidworth Military Hospital

PULMONARY moniliasis, though rare, is probably commoner than is generally supposed. In a study of over a thousand sanatorium patients with pulmonary disease Keiper (1938) attributed no less than 2.9% of the infections to monilia. Acute pulmonary moniliasis following the exhibition of antibiotics is described by, among others, Ormerod and Friedmann (1951), Wolff (1952), and Browne (1954).

CASE-RECORD

Pte. A, aged 21, was transferred to Tidworth Military Hospital on Dec. 8, 1953.

Three days previously he had been admitted to a neighbouring medical reception station with retrosternal pain and shortness of breath of a few hours' duration; he had little cough, and it was unproductive. On admission to the reception station he had a temperature of 102°F, and signs of consolidation at the base of the right lung. A diagnosis of pneumonia was made, and penicillin treatment was begun. Next day his temperature was 104°F and the pain in his chest was worse. Despite treatment with sulphadimidine his temperature again reached 104°F, and he was acutely ill; the signs of consolidation at the right lung base persisted.

When admitted to Tidworth Military Hospital he had had about 500,000 units of penicillin intramuscularly and about 6 g. sulphadimidine by mouth. He said that he had had drenching sweats during the past three nights. His previous history was not relevant: before being called up, he had been working as an electrician.

He was now acutely ill, and orthopnoic though not cyanosed. His temperature was 99.4°F. The mouth and fauces were normal and no enlarged glands were found. His cardiovascular system was normal: blood-pressure 120/90 mm. Hg. In his chest, impaired tactile vocal fremitus,

Chart showing patient's temperature in relation to treatment given: (A) sulphadimidine 6 g. and penicillin 500,000 units; (B) penicillin 4,800,000 units; (C) aureomycin 4 g.; (D) potassium iodide gr. 80 daily

dullness to percussion, and diminution in air-entry at the right base suggested consolidation with effusion. Radiography showed consolidation at both bases, especially the right. All other systems appeared normal, and the optic fundi showed no changes.

Sputum culture and examination revealed no predominant organism and no acid-fast bacilli with Ziehl-Neelsen staining. The white-cell count was 12,900 per c.mm. (polymorphs 72%, lymphocytes 18%, monocytes 10%).

From admission until Dec. 11 he was given intramuscular penicillin 200,000 units in saline solution four-hourly. Nevertheless his condition deteriorated rapidly. On Dec. 10 his respiration-rate was 40 per min. and he was in great distress, being confused, cyanosed, and at times delirious. On the right side bronchial breathing could be heard as high as the 4th intercostal space posteriorly. He was placed in an oxygen tent. That night his temperature rose to 104°F (see figure) and he was sweating profusely, though feeling cold. At 10.30 p.m. he had a sharp hæmoptysis and coughed up about an ounce of sputum, much bloodstained. A report on this sputum stated that it contained spores and (?) mycelia.

On Dec. 11 penicillin was discontinued, after a total dose in Tidworth Military Hospital of 4,800,000 units. During the next four days aureomycin 4.0 g. was given.

On Dec. 14 there were signs of fluid on the right side of the chest, and a diagnostic aspiration yielded 60 ml. of fluid, bloody but not turbid. The report on this was:

Micro-organisms.—None seen on Gram or Ziehl-Neelsen staining. *Cultures*.—Forty-eight-hour cultures (blood-agar aerobic and anaerobic) sterile.

Cytology.—Red blood-cells 5800 per c.mm.; white cells 17,200 per c.mm. (polymorphs 66%, lymphocytes 34%).

Chemistry.—Protein 3.0 g., sugar 130 mg. per 100 ml.

On Dec. 16 a further 60 ml. of fluid (deep orange in colour) was removed. The sputum now yielded *Staphylococcus albus*, *Neisseria catarrhalis*, and *Streptococcus viridans*, and in addition a few monilia (candida) colonies. Culture on Sabouraud's medium produced a heavy pure growth of *Candida albicans*, and on four subsequent occasions this organism was grown from the sputum.

From Dec. 15 onwards no antibiotics were given, and from Dec. 19 the patient received potassium iodide gr. 80 daily. The effect was dramatic: his temperature fell to normal within thirty-six hours (see figure) and he felt much better. By this time, however, there were signs of effusion on the left side, confirmed by radiography. Aspiration on the left side (Dec. 21) yielded 35 ml. of orange-yellow fluid containing red blood-cells 5600 per c.mm., and white cells 10,900 per c.mm. (polymorphs 58%, lymphocytes, 34%, monocytes 8%). No organisms were seen, and culture on blood-agar and on Sabouraud's medium was sterile after forty-eight hours. At two further aspirations on the left side a further 25 ml. of orange-red fluid was removed. The report for Jan. 5 was:

Micro-organisms.—None seen on Gram or Ziehl-Neelsen staining. *Cultures* on blood-agar (aerobic and anaerobic) negative.

Cytology.—Red blood-cells 14,400 per c.mm.; white cells 5900 per c.mm. (polymorphs 28%, lymphocytes 68%, monocytes 4%).

Chemistry.—Protein 3.0 g., sugar 130 mg. per 100 ml.

Improvement continued. On Jan. 20 radiography showed complete resolution at the right base and only pleural thickening on the left diaphragm, and on Feb. 1 the only abnormality seen was a pericardio-phrenic adhesion on the left side.

The patient has remained perfectly well and after a period of convalescence has gone back to full duties. He has not returned for follow-up, and it is not known whether or not his sputum still contains *C. albicans*.

COMMENT

Castellani in 1905 was the first to report primary bronchomoniliasis (Castellani 1910). He later maintained that the condition could be diagnosed only if tubercle bacilli were absent from the sputum and monilia constantly present (Castellani 1928). Ikeda (1936) distinguished three main groups of pulmonary moniliasis:

- (1) *Mild*.—Cough and scanty sputum.
- (2) *Moderate*.—Cough, sputum, and low-grade fever.
- (3) *Severe*.—Dyspnoea, night sweats, cough, sticky glairy sputum; exacerbation resembling acute lobar pneumonia; chest pains, hæmoptysis.

Cases of pleural exudate have been described (Koerth et al. 1941, Warr 1931).

In the case we report here, our reasons for diagnosing moniliasis were: (1) the absence of leucocytosis at height of the illness; (2) the absence of tubercle bacilli in the sputum; (3) the presence of *Candida albicans* in the sputum; (4) the resemblance of the symptoms and signs to those described by Ikeda as characterising the severe form of pulmonary moniliasis; (5) the failure to respond to antibiotics; and (6) the dramatic response to iodides (Wylie and De Blase 1944).

New Inventions

A KNIFE FOR MITRAL VALVOTOMY

In most cases of mitral stenosis it is possible to enlarge the mitral orifice adequately by splitting the commissures with the index finger. Sometimes the commissures do not yield to this force and have to be cut. Since this is a blind procedure, it is very important to retain a sense of touch so that it is the commissure that is divided and not any other part of the valve.

The instrument illustrated here has a small crescentic cutting blade made in one piece with a steel spring clip which can be slipped over the tip of the index finger. A rubber stall is worn over the instrument to assure that it does not come off the finger; the blade cuts through the rubber of the fingerstall as it engages the commissure.

This instrument allows the sensitive tip of the finger to explore in advance of the knife, and ensures that the blade is applied in exactly the right place and in the right direction. Worn in the manner illustrated, with the blade over the pulp of the finger, it is used for dividing the anterolateral commissure. To cut the posteromedial commissure it may be reversed so that the blade is over the finger-nail.

For the design and manufacture of this instrument I am indebted to the late Mr. R. Schranz, whose sudden death last year was such a sad loss to British thoracic surgery. It is made and supplied by the Genito-Urinary Manufacturing Co. Ltd.

ROYAL SOCIETY OF MEDICINE

Clinical Aspects of Immunity

At a meeting of the section of medicine on March 23, Sir HENRY COHEN, the president, introducing the speakers, commented on the appropriateness of discussing immunity problems during the centenary year of Ehrlich's birth.

Prof. A. A. MILES, discussing bacterial immunity, dealt mainly with the selection of appropriate antigens for active immunisation and with difficulties of clinical trials of new prophylactics.

Prof. A. W. DOWNIE surveyed virus infections, and he contrasted diseases such as poliomyelitis in which only a few persons exposed to infection developed clinical symptoms, with measles and smallpox in which nearly all persons encountering the infective agent for the first time developed the disease. In smallpox the fall in temperature and apparent improvement in the patient's condition was associated with the appearance of antibodies in the blood-stream and the disappearance of free virus particles, but the virus already present in the tissue cells was protected from antibody attack and caused the later symptoms and finally death. Hence it was important that protective antibodies should be administered to contacts before the end of the normal incubation period and before the viruses gained access to the tissue cells.

Prof. B. G. MÆGRAITH spoke on protozoal infections and offered advice on the treatment of different malaria patients. A patient such as an Indian seaman who was likely to be exposed to fresh infection should have his immunity preserved; he should be treated with a drug such as mepacrine which would clear up the current attack by removing parasites from the blood-stream without affecting the reservoir of exoerythrocytic forms. On the other hand, in, for example, a National Serviceman returned from Korea or Malaya it was necessary to eradicate the infection completely, and drugs such as proguanil which dealt with the exoerythrocytic forms should be used. It had been found accidentally that a milk diet suppressed malarial infections, and this accounted for the fact that in malarial districts breast-fed infants escaped infection, while after weaning young children were highly susceptible to malaria until immunity developed. Thus dietary and other factors could influence resistance to disease without affecting basal immunity.

Both Prof. ROBERT CRICKSHANK and Mr. A. FELIX, D.S.C., F.R.S., commented on the interference by antibiotics with the development of immunity following bacterial infections. Relapses occurred since these antibacterial agents rapidly reduced the number of infecting organisms below the level at which they provided sufficient antigenic stimulus to immunise the patient. This was seen particularly in infections with hæmolytic streptococci, typhoid bacilli, and brucella.

Dr. DOUGLAS MCCLEAN, who had recently returned from a conference on immunisation arranged by the World Health Organisation, made a plea for the establishment in this country of a pool of gamma-globulin from the plasma of persons who were convalescent from various diseases, or who had been recently immunised. Globulin from Service recruits recently vaccinated would be valuable for the treatment of smallpox, and globulin

from rubella convalescents could be used for the protection of pregnant women.

In winding up the discussion, the PRESIDENT felt that in clinical trials adequate controls could be maintained without withholding valuable treatment from those needing it. He questioned whether some bacterial antigens were really entities or merely names without substance.

Reviews of Books

Modern Trends in Dermatology

2nd series. Editor: R. M. B. MACKENNA, M.D. Camb., F.R.C.P., physician, dermatological department, St. Bartholomew's Hospital. London: Butterworth. 1954. Pp. 327. 63s.

THIS is a complementary volume to the first series published five years ago. Progress in dermatology in these years has been extensive, and this book gives a clear idea of the most important advances. Of the 17 chapters, 7 are by dermatologists and the remainder by writers in other specialties directly or indirectly related to dermatology. In his introduction Dr. MacKenna wisely advises the reader not to follow the classical custom of beginning at the beginning and going on until he comes to the end: for the subject matter, though in orderly arrangement, is diverse, and the reader will find himself subjected to abrupt changes of thought—leaping from psychosomatic medicine to anatomy, or from cortisone to beta rays.

Especially good chapters, with a practical bearing, include those by Shooter on the use of antibiotics, Sulzberger and Rose on cortisone and corticotrophin, Pillsbury and Kligman on cutaneous bacteriology, Baer on cross-sensitisation, Haserick on lupus erythematosus, and Dowling and Wetherley-Mein on cutaneous tuberculosis. Banks gives the book a good start and a broad outlook with his opening chapter on the changing pattern of skin diseases since the 16th century, and outlines prospects for the future with special reference to an ageing population.

Altogether this is a stimulating and thought-provoking work, a worthy companion for its five-year-old sibling. References are comprehensive.

Le Leptospirosi

MARIO AUSTONI, aiuto dell'istituto di patologia medica e incaricato di malattie infettive nella Università di Padova. Padova: Tipografia del Seminario di Padova. 1953. Pp. 706. L. 5000.

Professor Austoni's extensive monograph falls into two parts. In the first, which deals with leptospire as micro-organisms, he describes their morphological and cultural characteristics.

He agrees with *Bergey's Manual of Determinative Bacteriology* in placing the genus in the order Spirochaetales, and the family Treponemataceae. He holds that the genus is most conveniently subdivided according to antigenic composition since that is a specific and stable character. By contrast, association with carrier-hosts, and differences in pathogenicity, in geographical distribution, and in the clinical picture in man are not sufficiently characteristic to be of value for this purpose. But each species of leptospire has its carrier-host of election, and differences in the ecology of these hosts and in their associations with man and domestic animals is of importance in choosing the most appropriate preventive measure. Hence Professor Austoni has therefore included a chapter on carrier-hosts.

The second, and much the longer, part of the monograph is concerned with leptospire as pathogens. It is no easy task to give a comprehensive survey of leptospirosis in man and animals, for more than thirty different species (or serological types) are known. A single type may produce quite different pathological changes in different species of animals, and strains of the same serological type may evoke different illnesses in individual hosts. Nevertheless there are certain essential features common to all forms of leptospirosis—e.g., the importance of urine-contaminated water in transmission, and the potential capacity of all species to attack the liver,

kidney, and meninges—and Professor Austoni has skillfully used these features in drawing a general picture of the condition in man. He then takes each of the more important species of leptospire separately, and shows how their differences are reflected in the epidemiology and the clinical manifestations of the disease they produce. This plan has some disadvantages, since the different aspects of infection with a single species are not treated as a complete entity: the casual reader, interested perhaps in one form of leptospirosis, may find difficulty in piecing the details together. But the method obviates endless repetition, and has allowed Professor Austoni to make good use of a wealth of material.

The monograph is well printed on good paper with many illustrations. The bibliography contains nearly 3000 references.

Anatomy and Surgery of Hernia

LEO M. ZIMMERMAN, M.D., professor of surgery and co-chairman of department of surgery, Chicago Medical School; BARRY J. ANSON, PH.D., professor of anatomy, Northwestern University. Baltimore: Williams & Wilkins. London: Baillière, Tindall, & Cox. 1953. Pp. 374. 76s 6d.

THIS is a well-produced, profusely illustrated, readable, and informative book on the condition which most commonly needs to be submitted to surgery—hernia. It has been written jointly by a professor of surgery and a professor of anatomy, and, as they say, "the anatomical studies go beyond the usual morphological descriptions." Indeed, more than 40 pages are dedicated to a detailed description of the abdominal wall before the anatomy of hernia is specially considered. In the opening chapter due credit is given to the pioneer work of Marcy. Each type of abdominal hernia is considered separately and thoroughly, and a special chapter is devoted to hernia in general. Good judgment is shown in reviewing the various methods of treatment in vogue. The injection treatment is not recommended (except for very special cases), and concerning the use of fascial sutures the authors do not commit themselves.

This is too big a book for the student, and the junior surgeon would probably ask for greater detail on the operative relief of strangulation; in fact, it is a work of reference for the experienced surgeon. But there are no illustrations in it to equal any of the plates in the classical book on hernia by Astley Cooper (who appears in the references to the historical section simply as "Cooper, A. P.").

Hypertensive Diseases

Causes and Control. H. A. SCHROEDER, M.D., F.A.C.P., associate professor of medicine and director, hypertension division, department of internal medicine, Washington University School of Medicine. With contributions from G. S. GRESSL, M.D., D. F. DAVIES, M.D., K. M. PERRY, jun., M.D., and D. F. GIBBS, M.R.C.P.E. London: Henry Kimpton. 1953. Pp. 610. 75s.

THIS book will be welcome. All but a few chapters are the work of Dr. Schroeder, who, besides being an authority on its complex subject, has a talent for exposition.

The first half is mainly a documented survey of what is known about the pathogenesis of hypertension. In discussing renal pressor factors Dr. Schroeder tells how he and his colleagues isolated pherentasin, an amine compound which is said to be the only pressor agent consistently found in the blood of hypertensives but not of normotensives.

The rest of the book describes hypertensive conditions and their treatment. Three main types—neurogenic, nephrogenic, and endocrine—are postulated. Dr. Schroeder's conception of endocrine hypertension is broader than the conventional one, but he makes out a good case for it. Some of his cases of neurogenic hypertension, however, would not ordinarily be regarded as truly hypertensive, for at rest their blood-pressure was normal. Dr. Schroeder may be right in so labelling them, but he does not give evidence that these intermittent hypertensives deteriorate, as is implied by calling their condition stage I of neurogenic hypertension. The absence of an adequate discussion of prognosis is in fact a disappointing feature of the book: our knowledge of the natural history of hypertension is admittedly not great, but he does not do it justice.

Dr. Schroeder makes a strong claim for the efficacy of oral treatment with a combination of 1-hydrazinophthalazine

('Apresoline') and hexamethonium. The effect on 250 patients over a period of two or three years is said to have been "little short of miraculous."

This is not a book for the student or intern, for much of it is controversial; but those with experience of hypertension will find it thought-provoking and important.

Carcinoma of the Female Genitalia

By HANS LUDWIG KOTTMEIER, M.D., chief, gynaecological section, Radiumhemmet, Stockholm. Baltimore: Williams & Wilkins for Vanderbilt University. London: Baillière, Tindall, & Cox. 1953. Pp. 213. 33s. 6d.

IN Sweden a cancer campaign is in progress, and cancer detection departments have been established at the three main clinics, where anybody who fears he has cancer can be examined. Kottmeier notes that, at the Radiumhemmet, fundamental changes in technique and methods of treatment are never made until the new technique in use has received a thorough trial; and the success obtained at this centre is no doubt largely due to this policy. The uncritical use of irradiation has brought radiotherapy into disrepute in some other countries; and radioactive isotopes and supervoltage X-ray therapy may lead to a similar situation. As yet we know very little indeed about the use of these agents, and the need for caution is great.

Kottmeier reviews the various methods of estimating dosage-distribution in the pelvis, in the treatment of cancer of the cervix, and describes his own work in this field. In his view, combined radium and X-ray therapy is the treatment of choice. Almost 20% of stage-I cases have metastases, and it is here that X-ray treatment can play an important part. Charts and tables illustrate 5-year survival-rates, incidence of rectal and bladder injuries, and the sites of recurrences in apparently healed cancer of the cervix.

Cancer of the body of the uterus is on the increase. In Sweden its ratio to cancer of the cervix is 1:2.4, and hysterography has demonstrated that cervical involvement in cancer of the body is commoner than is generally believed. The results of radium treatment in this type of cancer, followed in cases of failure by surgery, compare favourably with the best results obtained by surgery alone. A 5-year survival-rate of 80.7% for cases in stage I, and 72.2% for cases in stage II, at the Radiumhemmet, compares favourably with the 64.7% 5-year survival-rate in cases treated surgically by Meigs and Morton. The claim that it is possible to control lymph-gland metastases by surgery and *not* by radiation is met by comparing statistics for cases treated surgically by Bonney in England and cases treated radiologically at the Radiumhemmet.

No-one interested can fail to profit from the information and instruction contained in this book. The text is profusely illustrated with statistical tables, charts, radiographs, and photomicrographs.

Introduction to Electronics for Physiological Workers

I. C. WHITFIELD, B.Sc., Ph.D., lecturer in physiology, Birmingham University. London: Macmillan. New York: St. Martin's Press. 1953. Pp. 236. 18s.

BOOKS such as this, which introduce electronics to physiological workers, are particularly useful now that medicine and physiology have assimilated many of the techniques of the exact sciences. It is an advantage to the physiologist to have some theoretical knowledge of light current engineering—electronics, as it has come to be called—since he has to employ thermionic valves for many measuring purposes.

There are books which describe circuits and electrophysiological techniques useful to physiologists; but, in attempting less, Mr. Whitfield's book possibly achieves more. He explains the elements of the subject lucidly and with practical understanding; and the student who works conscientiously through this book will begin to think in terms of electronic methods and electrical measurements, and will thus be enabled to devise apparatus to meet his particular needs. He should, however, remember that this is an abbreviated course, and should use caution in attaching electronic apparatus to himself or his patients without expert help. The chapters on noise and interference are especially commendable, and could only have been written by someone with much practical knowledge of the subject.

Vitamins and Hormones

Advances in Research and Applications. Vol. II. Editors: ROBERT S. HARRIS, professor of biochemistry of nutrition, Massachusetts Institute of Technology, Cambridge, Mass.; G. F. MARRIAN, professor of medical chemistry, University of Edinburgh; KENNETH V. THIMANN, professor of plant physiology, Harvard University, Cambridge, Mass. New York and London: Academic Press. 1953. Pp. 356. \$8.50.

THIS eleventh volume, built up on the lines of the preceding ones, contains 8 articles written singly or jointly by 13 experts in their own fields; and it will appeal to physicians and physiologists because it contains more of direct human interest than some of its predecessors.

A historical and rather critical article on the biochemistry and physiology of vitamin D, by R. Nicolaysen and N. Eeg-Larsen, is matched by a good one on ascorbic acid by A. P. Meiklejohn. L. W. Mapson has contributed an article on the function of ascorbic acid in plants, and S. Zubiran and F. Gomez-Mont have a section on endocrine disturbances in chronic human malnutrition which is largely an account of their own clinical findings in Mexico. Many will read with interest the account of the biochemistry of the thyroid gland by J. Gross and Mrs. Pitt-Rivers, which includes all the recent work on the active triiodothyronine. The remaining articles deal with the relation of pantothenic acid to adrenal cortical function, the evaluation of procedures for the cytological localisation of ketosteroids, and the synthesis of cortisone and related steroids. The last, by C. Djerassi, will be appreciated by the select few, but it is not exactly fireside reading.

This volume carries a cumulative subject index for the last 5 volumes and its own subject and author index. The editors have spared themselves no trouble which might enhance the reputation of their series, and are to be congratulated on the result.

Practical Procedures in Clinical Medicine (2nd ed. London: J. & A. Churchill. 1954. Pp. 484. 32s.).—The second edition of this practical account of biochemical and radiological investigations in clinical medicine includes procedures and techniques which have come into general use since the first edition appeared in 1950. Dr. R. I. S. Bayliss has again aimed at providing enough detailed information to enable residents and others to carry out many of the investigations described; more complex tests are described less fully, but their physiological basis is clearly stated. It is interesting that the four pages of clear description of the electrocardiographic leads included in the 1950 edition are now reduced to about half, while several pages are devoted to cardiac catheterisation—not previously dealt with. Many of the subjects, such as a fairly full posological table and a section on dietetics, seem rather outside the scope of the title. The chapter on radiology in clinical medicine remains most helpful, and this edition will certainly retain its predecessor's popularity, especially among housemen and those sitting for higher examinations.

An Introduction to Pathology and Bacteriology for Medical Students in the Tropics (2nd ed. London: Staples Press. 1953. Pp. 390. 50s.).—This book, originally written by the late Dr. E. C. Smith and now revised by Prof. R. Kirk, is intended for medical students in tropical schools. It was conceived as an introduction to, not as a substitute for, the existing textbooks, and it is not a "practical manual" but an exposition of the intimate relation between pathology and bacteriology, and between these subjects and clinical medicine.

The pathological section comprises chapters on disturbances of metabolism and circulation, inflammation, tumours, infection and resistance; but the remaining sections also contain much pathology. There are chapters on bacteria and the diseases caused by them, pathogenic fungi, viruses and rickettsia, spirochaetes, protozoa, and helminths. Others follow on diseases of the blood, the endocrine organs, the liver and other abdominal organs, and four appendices deal with lymphadenopathy, post-mortem technique, stains, and culture media. So large a range of subjects obviously can only be dealt with in outline, but the virtue of the book is that it brings these subjects conveniently together, and it is well fitted for use in conjunction with lectures which amplify and explain the terms and processes here succinctly described. The illustrations (photographs, photomicrographs, and coloured drawings) are very good.

ALFICETYN PRODUCTS

Containing British-made Chloramphenicol

Simplify the treatment

ALFICETYN CAPSULES. For oral administration. Available in bottles of 12 capsules each containing 0.25 gramme Chloramphenicol B.P.

ALFICETYN EAR DROPS. Containing a 10% solution of Chloramphenicol B.P. in vials of 5 c.c. with a suitable dropper applicator.

ALFICETYN DUSTING POWDER. Providing 5% Chloramphenicol B.P. in a sterilised, free-flowing diluent. Supplied in sprinkler-topped vials of 5 grammes.

A pleasantly flavoured elixir for the menopausal patient

The association of methyltestosterone and ethinylœstradiol in Mepilin produces a more complete response in the treatment of menopausal disorders than can be obtained by the use of œstrogens alone.

The presence of methyltestosterone enables a reduction in œstrogen dosage to be made; thus undesirable side effects such as breast turgidity and pelvic congestion are avoided and the risk of withdrawal bleeding is reduced. An increased feeling of confidence and well-being is produced which is both mental and physical.

'MEPILIN' TABLETS & ELIXIR

Each teaspoonful (4 ml.) of Mepilin Elixir and each Mepilin Tablet contains ethinylœstradiol 0.01 mg. and methyltestosterone 3 mg.

'MEPILIN' TABLETS
Bottle of 25 at 4/4 and 100 at 14/6
'MEPILIN' ELIXIR
Bottle of 4 fl. oz. at 6/- and 20 fl. oz.
at 23/-.
Basic N.H.S. prices

DOSAGE: Menopause and geriatric conditions: average cases—3 tablets or 3 teaspoonfuls daily. Premenstrual tension and dysmenorrhœa—2 tablets or 2 teaspoonfuls daily from 10th to 22nd day of the menstrual cycle.

Literature and specimen packings are available on request

LONDON: SATURDAY, APRIL 3, 1954

Who is to Pay for Mistakes?

In the litigation of the past few years an unifying situation has occasionally arisen in which a hospital authority, in defending itself against a charge of negligence, has provided evidence against its own medical staff. Moreover, under an instruction issued in 1949 by the Ministry of Health, a hospital authority which has to pay damages to a patient is expected to reduce its own pecuniary loss by obtaining, through legal process, a contribution from any member of its staff whom it regards as negligent. Thus administrators and doctors, who should always be partners in a common task, have sometimes become antagonists, whether actual or potential, to the detriment of the service. In the hope of putting a stop to this state of affairs, the medical defence societies and the British Medical Association have asked the Minister to withdraw his 1949 instruction, and this has now been done. Under an agreement embodied in the Ministry's circular which we summarise on p. 727, hospital authorities are told to consult with the defence societies—preferably before the court hearing—and if possible reach agreement on the proportion of damages that each should pay in the event of damages being awarded. If the defence society and the hospital authority cannot agree, each is to pay half.

The first reaction to these arrangements will be one of relief. Given the amicable co-operation on which we may fairly count, they should reduce friction and will often lead to fairer decisions. Our impulse, then, is to congratulate the Ministry and the professional organisations on a success for good will and common sense. But before expressing unreserved approval we should perhaps examine the implications a little more closely. Is there not some risk that, perhaps imperceptibly, the new system may weaken the independence of the profession? Professional freedom and professional responsibility are two sides of the same medal; and if the doctor is to be free he must also be responsible—responsible not only for his successes but likewise for his failures. If it should ever come to be thought that the State, as his employer, ought to pay the cost—or even part of the cost—of his mistakes, he must to that extent become its employee, and be bound to do its bidding.

Do the new arrangements really contain this risk? We do not, of course, know exactly how they will work; but presumably if a defence society thinks that its member really has been negligent, and that the responsibility rests on him alone, it will offer to pay all the damages awarded. So far so good. If, on the other hand, it thinks that, though its member is to blame, some part of the responsibility rests on non-medical members of the hospital staff or on the administration, it will offer to pay only an appropriate share of the damages. Again that would be right. But if, as may often happen, it feels that, though there has been an accident and the patient has suffered thereby, the doctor has been more unlucky than culpable, may it not be tempted to urge that the damages should be paid by the hospital—that is to say,

by the service rather than by the profession? The reputation of the profession could be in no safer hands than those of the wise and experienced people who run our defence societies; but unless they are provided (as they should be) with funds sufficient to make money no object, they can hardly be expected to insist on paying in full damages which the Ministry is ready to share. The temptation to avoid, on behalf of their members, apparently unnecessary obligations will surely be enhanced by the provision that, if no agreement is reached, the Ministry and the profession shall each pay half. Should such friendly compromise ever become the norm, regardless of the merits of the individual case, then indeed will our professional position be imperilled.

Are we exaggerating? Is there any real threat to this position? Consider the following passage from Mr. SPELLER's handbook¹ published this week by the Royal College of Nursing:

"All the staff of the teaching hospital, medical and non-medical alike—with the possible exception of part-time consultants—are servants of the board of governors, i.e., they work under a contract of service. The staff of a non-teaching hospital, with the same reservation, are servants of the regional hospital board, though, except in the case of senior medical staff, the power of appointment and dismissal is, by regulation, delegated to the hospital management committee. Throughout these notes, therefore, we shall for practical purposes treat the hospital management committee as the employer or master."

Unhappily these words do fairly represent legal opinion in England (though not in Scotland) today; and, unless this English opinion is reversed by the House of Lords, it looks as though the profession either will have to accept the relationship of hospital authority and doctor as that of "master and man" or will have to negotiate a change in the terms of service of the N.H.S. so that doctors are paid through professional bodies and not by lay boards. Meanwhile it should, we believe, be careful to do nothing that might weaken the principle that the doctor, being responsible first and foremost to his patient, must use his own judgment in discharging that responsibility and must accept the consequences of his errors. When the other day we insisted on this professional freedom of judgment,² the *Manchester Guardian*³ argued that where, in what he held to be the interest of the patient, a surgeon deliberately took a risky course, his decision would be upheld by any good hospital authority. That is true; and the good "employer" of doctors will certainly want to back them when some personal issue of conscience is presented thus forcibly—in some sort of *cause célèbre*. But this will not necessarily prevent a slow change of climate in which caution and conformity flourish and control takes root. If, over the years, it were accepted that hospital authorities ought to go shares in any damages awarded against their doctors, they would be justified in introducing more and more small rules for doctors—indeed they would feel obliged to do so. A situation would thus arise which the Ministry of Health has so far scrupulously avoided, in which clinical work was exposed to lay regulation; and even if (as is doubtful) such regulation

sometimes prevented negligence, the damage it would ultimately do to the work of doctors would far outweigh, for the public, the advantage thus gained. Fortunately this situation is one which, through the defence societies, we can, if we wish, avert. If we think professional freedom more important than money—if we are not prepared to sell our professional birthright—we must insist that when we do make mistakes we pay for them ourselves.

The Curability of Cancer

WHILE we acclaim new methods of treating cancer by radical surgery and radiotherapy, the death-rate from that dread disease abates little. The comparative mortality index, which allows for changes in the age structure of the population, shows for men a rise of 6% in cancer mortality between 1938 and 1950, and for women a fall by the same amount. The small disparity between the sexes is almost entirely due to the relatively greater increase in the frequency of death from cancer of the lung among men. Even among women, however, the decline is small enough to give point to Professor MCKINNON's analysis¹ of our apparent failure in cancer control. In Saskatchewan, despite a long and intensive educational programme for the early detection and treatment of cancer, the death-rate from cancer of the breast shows no downward trend. This disappointing stability, MCKINNON finds, is shared by another Canadian province where no special measures have been taken. In Massachusetts, where an active drive for early diagnosis and treatment has been in progress since 1926, the trend of breast-cancer mortality, he says, is almost identical with that in England and Wales. Twelve years ago LOMBARD and MACDONALD² took a more optimistic view of the trend in Massachusetts, compared with that in the rest of the United States; but the small and equivocal improvement they claimed was disappointing in view of the apparent success of health education in persuading women to report suspicious masses in the breast. In Massachusetts the average delay between first sign and first consultation dropped from six months in 1926 to four months in 1948. In Connecticut similar methods resulted in a rise in the proportion of cases with "localised" breast cancer from 44 to 51% between 1940 and 1949, while five-year survival-rates increased from 21.7 to 27.6% between 1935 and 1944. Yet over these years the death-rate from breast cancer in the Connecticut population showed no sensible decline. Possibly simultaneous alterations in factors affecting both true and reported incidence may have masked a beneficial effect of cancer education and early treatment. With improved death certification there is greater likelihood of the breast, rather than an organ of metastasis, being named as the primary site.³ Again, a fall in the birth-rate may increase the proportion in the population of middle-aged multiparæ, who are especially prone to the disease. These and other factors could neutralise the results of therapeutic success and keep the death-rate steady. But that these influences should be precisely equal and opposite seems unlikely. Some better explanation is required.

3. Bigelow, G. K., Lombard, H. L. *Ibid.*, 1934, 210, 527.

The basic reason for aiming at prompt detection and treatment of cancer is that the survival-rate is greater in cases treated before metastatic spread is apparent than in those with metastases: if only it could be taken in time, the argument runs, cancer of the breast would usually be curable. There is an implicit assumption that nearly all neglected cancers enlarge and spread by the lymphatics, and that radical treatment will cure a small localised, recently discovered, tumour. MCKINNON, however, takes the opposite view, concluding that in "most, if not all, lethal breast cancer remote spread takes place via the blood-stream before interference is practicable"; and in this heresy he is not alone. The survival-rates after different periods of delay before seeking medical advice often show a curious paradox. Thus SWYNNERTON and TRUELOVE,⁴ reviewing 395 cases of gastric carcinoma, showed that the greater the delay and the longer the history of symptoms, the greater was the survival-rate; and their findings are neither novel nor singular. BLOOM,⁵ for example, showed that, in patients with cancer of the breast who had had symptoms for six months or less before operation, the five-year survival-rates were certainly no better than for patients who had had symptoms for a year or more. KREYBERG⁶ cites reported series where symptoms had been noticed for less than four weeks and yet the five-year survival-rate was only 50%. He notes, too, that the size of the primary tumour is no guide to its curability; two-thirds of patients reporting with tumours of the breast which were smaller than a hazel nut already showed metastases.

This apparent paradox is explained by the overwhelming importance of the growth-rate of the tumour. In ascribing to early treatment the higher survival-rate in stage-I breast cancers compared with those in stage II, we assume that we are comparing like with like. But the apparently curable stage-I cancers may consist of slowly metastasising tumours, whereas those first seen in the late stages may mostly be rapidly invasive and metastatic tumours whose brief initial stage escaped notice. In other words, the stage of the disease is a function, not of time, but of the tumour type. As LEES and LEES point out,⁷ when inoperable or untreated cases are followed up until death⁸ the natural survival-time proves longest in just those cancers—of breast, rectum, or cervix uteri—which are usually thought to be most amenable to treatment. LEES and LEES note, too, that the variability between individuals in survival-time is proportional to the mean survival-time for all untreated patients with the same type of cancer. In cancer of the breast a patient may survive for a long time even without treatment, and individual instances of long survival after operation are therefore no proof of the operation's efficacy. Such differences, found even in inoperable patients, bespeak major difference in tumour malignancy or host susceptibility, and they suffice to explain the unexpected association between length of delay before treatment and five-year survival—for example, in cancer of the stomach. MACDONALD and KOTIN⁹ have re-stated views suggested by

KORTEWEG in 1880. In the period of delay a "natural selection" of cancers of relatively low malignancy takes place through the elimination, by the patient's death, of the more rapidly metastasising tumours. Any group of patients operated on shortly after the onset of symptoms will contain both rapidly metastasising and relatively much less malignant tumours. With longer delay patients with more rapidly lethal cancers will die, leaving a higher proportion of less serious tumours.

Because of the supposed need for early diagnosis and treatment, chest radiographs and self-examination of the breast have been suggested as appropriate methods of detection. If recent experience is typical, however, by the time definite abnormality appears on the radiograph,¹⁰ most cases of pulmonary cancer have progressed too far for successful resection; and an apparently normal radiograph can be followed by death within a year. As KREYBERG suggests, there may be an intermediate group of cancers amenable to early excision, but if the disheartening views on the rapid lethality of most cancers and the irrelevance of early treatment are to be believed, no great improvement in mortality can be expected from such measures. It would be much better to treble the tax on tobacco.

In ordinary practice other considerations arise. The palliative effect of local resection of tumours causing physical difficulties is indisputable. On the other hand hazardous and mutilating radical operations for removal of the breast are less clearly desirable: as Professor MCKINNON emphasises in a letter in this issue, survival-rates after simple excision, radical mastectomy, and irradiation are depressingly uniform.¹¹ Vital statistics give only a general indication of the results of treatment; and the statistical pitfalls of assessing the value of treatment by comparing the results in consecutive series of patients in the same hospital, or of different series at different centres, are now well known. BLOODGOOD¹² pointed out that education of the public will bring to the hospital an increasing number of patients with a mass in the breast which is not a lethal cancer at all but which, when included in reported series, will inflate the survival-rates. Similarly, the inclusion of different proportions of such tumours in series treated in different clinics can cause wide divergences in survival-rates which are unrelated to the different methods of treatment.¹³ Neither by clinical examination nor by biopsy can such tumours be unerringly classified as benign or malignantly metastatic, and the histopathologist's opinion (which is subject to little-studied "observer-error") cannot be relied on to equate the clinical material on which rival claims are based. Cancer registration may, when complete, provide useful epidemiological evidence. But since it lacks the essential feature of random allocation of treatment to patients it is no effective substitute for the carefully controlled clinical trial now practised in other branches of medicine.

Our basic approach may be wrong: the attempt to treat cancer as a local rather than a general disease may be as irrational as treating syphilis by excising the primary chancre. Although there is no clear

evidence either way, the value of drastic remedies is uncertain enough to justify, as a first step, treating half our patients in a controlled trial by simpler methods. By a progressive elimination of the more drastic remedies whose value is not confirmed by clinical trial, we may eventually assess the place of local measures in the treatment of cancer. Surely the time has come for a realistic and unbiased appraisal?

Dyspnoea and the Work of Breathing

By dyspnoea is usually meant excessive subjective respiratory effort. As patients' judgments are not always reliable it is natural to seek an objective measure of effort in the work performed in breathing. This work is used partly in moving the chest wall and abdominal viscera, but mostly in expanding the lungs and in driving air through the bronchioles; and this part can now be measured fairly easily. As long ago as 1927, VON NEERGAARD and WIRZ¹ pointed out that simultaneous records of intrathoracic pressure and respiratory airflow enabled the work to be further analysed into a portion used in overcoming the retractile force of the lung and another overcoming the resistance to movement. By such analysis one could assign to the patient's lungs and air-passages a pressure-volume characteristic (elastance) and a pressure-movement characteristic (viscance), and so calculate the work entailed by a specified pattern of respiration. By direct measurement of intrapleural pressure and airflow, VON NEERGAARD and WIRZ obtained excellent records in a few subjects; but since their method was difficult and potentially dangerous it was not widely used. The theory was developed by FENN and his colleagues,^{2,3} who showed that for a given net (i.e., total less dead-space) ventilation the respiratory work passed through a minimum as the rate was varied. This optimum rate increased with increasing net ventilation and also if elastance was increased with respect to viscance. With the introduction by DORNHORST and LEATHART⁴ of a simple and convenient method of recording intrathoracic pressure through a fine oesophageal tube, these theoretical ideas can now be safely applied to the investigation of patients.

A recent series of papers by CHRISTIE and his colleagues⁵⁻⁷ demonstrates that in patients with emphysema and cardiac dyspnoea the work of breathing is increased—because of increased viscance in the former and increased elastance in the latter. Moreover, in normal people and in cardiac patients, at rest and during exercise, the actual respiratory-rates were close to the calculated optimum. Loss of lung distensibility during cardiac dyspnoea is probably related to an increase in pulmonary capillary blood-pressure, but the exact mechanism is obscure. The high viscance of emphysema is probably due to hindrance to airflow, since FRY et al.⁸ found very good agreement between the calculated and observed increase on breathing an argon/oxygen mixture which

was denser and more viscous than air. These workers also confirmed the remarkable rise in airway resistance as emphysematous lungs are emptied,⁹ which is probably due to collapse of bronchioles in the absence of elastic tension from surrounding lung.¹⁰

In the common forms of dyspnoea, then, breathing is in fact harder work; but this is not the whole story since the capacity for respiratory work is often impaired as well. The importance of this factor is seen, for example, in poliomyelitis with respiratory involvement, where a mild increase in airway resistance due to bronchitis may cause urgent dyspnoea because the patient can scarcely manage the work needed to maintain ventilation. In emphysema, too, the force that can be applied to the lungs often falls off quickly with movement, and this is one of the factors limiting vital capacity and maximal respiratory work.¹⁰ So the patient is entitled to have his effort assessed in relation to his own possible maximum, and this is the basis of the "dyspnoea index" of HUGH-JONES and LAMBERT,¹¹ where the patient's actual ventilation during standard exercise is compared with his maximal

breathing capacity. This formula does justice to those patients whose ventilation on exercise is above normal: these usually have mild mechanical trouble but, because of diffuse lung changes, a considerable decrease in the effectiveness of ventilation; they are apt to be regarded as neurotic.

Dyspnoea in organic disease can therefore be taken as reflecting an increased excitation of the respiratory centre, whether or not this results in greater respiratory work, and whether or not the greater work results in greater ventilation. The sensation would be excessive in quantity but normal in quality. However, it is as well to remember the possibility of dyspnoea arising from some abnormal sensation: for example, an adrenaline infusion produces a moderate hyperpnoea involving no great effort,¹² but accompanied by a peculiar sense of respiratory unease quite distinct from that in other forms of hyperpnoea though probably akin to that felt by patients with psychoneurotic effort intolerance. In conditions such as mitral stenosis both types of dyspnoea may co-exist and make clinical assessment difficult. In such cases the oesophageal tube may be of practical value.

Annotations

AUREOMYCIN IN ATYPICAL PNEUMONIA

FOR five years aureomycin has been thought to benefit patients with primary atypical pneumonia. This view has rested largely on accounts of small trials which have not been suitably controlled. Sometimes the diagnosis was in doubt, and the effect of treatment was usually evaluated only by decrease in fever and malaise. Two carefully controlled studies have lately been made in the U.S.A., but the authors come to opposite conclusions.

Major Walker, of the William Beaumont Army Hospital, Texas,¹ investigated the effects of aureomycin during an epidemic at Fort Bliss, Texas, where the patients were mainly young soldiers in basic training. Age, sex, race, physique, nursing, nutrition, and other variables were as uniform as they could possibly be. Duration of disease before treatment, severity, and symptoms were very similar in treated and untreated groups. Initial diagnosis was based on gradual and progressive development of fever, malaise, frontal headache, cough, and substernal pain, with or without physical and radiographic signs of alveolar pneumonia. Great care was taken to exclude such diseases as tuberculosis, oocidiosis, bacterial pneumonia, histoplasmosis, Q fever, and psittacosis. The 212 cases diagnosed as primary atypical pneumonia were divided at random into two groups; one group was treated with 0.5 g. aureomycin six-hourly until the temperature had been normal for at least three days, while the other group received no chemotherapy and served as a control. Walker found no significant difference between the two groups in the time taken for recovery. Comparison of duration of fever, physical signs, radiographic appearances, and major symptoms such as headache, malaise, cough, chest pain, and fever also showed no difference between the treated and the untreated patients. From this carefully controlled trial it would seem that aureomycin has no beneficial effect on primary atypical pneumonia.

Meiklejohn and his collaborators,² in California, examined the effect of various antibiotics on 146 young soldiers during an epidemic of primary atypical pneu-

monia. Only 30 were treated with aureomycin; the rest were given chloramphenicol, oxytetracycline (terramycin), or penicillin. The statistical treatment was less thorough than that of Walker's series, and the principal criterion of chemotherapeutic activity was a fall in temperature. Meiklejohn and his co-workers admit that a large proportion of patients will recover soon after admission to hospital, regardless of treatment; but they conclude that aureomycin is effective, and that chloramphenicol and oxytetracycline are no less useful. Penicillin in their hands gave disappointing results.

There are possible explanations of these apparently contradictory conclusions. Walker gave his patients aureomycin late in the disease—not until the fourth day—and the results might have been better if it had been given earlier. Eaton³ showed that aureomycin given to rats immediately after inoculation with the sputum of patients with primary atypical pneumonia inhibited the subsequent development of pulmonary consolidation. Meiklejohn and his collaborators treated their patients much earlier in the course of the disease; three-quarters of them were treated in the first or second day. Another explanation is that the virus may not have been the same in the two epidemics, one but not the other responding to chemotherapy. For the present it seems wise to treat primary atypical pneumonia with one of the orally administered antibiotics, such as aureomycin, oxytetracycline, or chloramphenicol, as soon as the diagnosis is made.

DUPUYTREN'S DISEASE OF THE FOOT

Dupuytren's contracture of the palmar fascia is a well-known disorder, but an analogous process involving the plantar fascia is less familiar. Pickren et al.⁴ cited 104 reported examples and added 16 of their own; and Pedersen and Day⁵ have now described the clinical and pathological findings in 6 further cases.

There are important anatomical differences between palmar and plantar fascia.⁴ Plantar fascia is much longer, narrower, and thicker; it arises from the anteromedial margin of the calcaneus and extends distally beneath the plantar fat and superficial to the muscles, tendons,

nerves, and vessels. The fascia fans out towards the forefoot, and the superficial fibres terminate in the superficial transverse ligament. Deeper, heavier components branch off before this and are inserted into the distal ends of the metatarsals in conjunction with the annular ligaments of the flexor tendons. Extension into the toes is absent or rudimentary; hence there is generally no counterpart in the foot to the flexion of the fingers which characterises Dupuytren's contracture of the palmar fascia. For this reason, Pedersen and Day prefer to speak of Dupuytren's disease when the foot is involved, while Pickren et al. called the condition "fibromatosis of the plantar fascia" because a nodule of proliferating fibroblasts is the presenting feature. A tumour-like nodule may also form in the palm; and pathologically there is no essential distinction between the processes in hand and foot. In the foot, however, in the absence of contractures and perhaps of pain, a nodule may easily escape notice, and the disorder may well be commoner than is realised.

The characteristic nodule (or nodules) in the plantar fascia is usually found on the medial side, near the highest point of the longitudinal arch,⁵ where it produces a visible and sometimes even prominent tumour. The mass may grow rapidly from the start, or begin to enlarge after long apparent inactivity. One or both feet may be involved. Of the 16 cases reported by Pickren et al., Dupuytren's contracture was also present in one or both hands in 6, while the condition of the hands was normal in 8, and was not recorded in the remaining 2; the thickened fascia was only occasionally adherent to the skin. Males seem to be affected more often than females, and the process may start in patients as young as 5 years of age. As in Dupuytren's contracture of the hand, a familial tendency can sometimes be discovered. In some cases there is exceptional liability to keloid formation, and the disease also has a curious and unexplained predilection for epileptics.

Pickren et al. described the lesion as consisting of lobulated, irregular, nodular thickenings of the plantar fascia together with the adjacent fat and fibrous tissue. The average size of the nodules was about $3 \times 2 \times 2$ cm.; they projected from the fascia chiefly towards the plantar surface, but sometimes deeply towards the dorsum of the foot. The medial aspect of the fascia was chiefly involved. Invasion of tendons, nerves, vessels, or bones was never seen. Microscopically the normal broad, cell-free collagen bands of the plantar fascia terminated in nodules of young fibroblasts and interdigitated with other bundles of highly cellular new tissue. No capsule was observed, and the marginal fibroblasts merged into the surrounding tissues. In the nodules and bundles spindle-shaped cells were sinuously interwoven, curving abruptly at sharp angles; the cells were closely packed, with scant intercellular collagen. Infiltration with leucocytes was rare. Occasionally large numbers of mitotic figures were seen. Pedersen and Day believe that the formation of nodules is a response to degeneration of the plantar fascia. They found nodules, never in areas of normal fascia, but only where the collagen fibres showed fibrillation, fragmentation, and hyalinisation. They interpreted increased numbers of thick-walled small vessels and focal collections of round cells as a response to a primary degenerative process, possibly related to trauma.

These careful histological studies, though yielding no fresh clue to aetiology, should help to prevent the unfortunate misdiagnoses which have occasionally led to unnecessary amputation.^{4 5} The danger is of interpreting the histological changes as fibrosarcomatous; the suspicion of malignancy may seem to be confirmed when a new mass appears at the site from which a nodule has earlier been removed. Fibrosarcoma of the plantar fascia is exceedingly rare,⁴ and local "recurrences" of Dupuytren's disease do not take place if it is correctly

treated by excision of the entire plantar fascia. Mistakes are less likely in cases where contracture of the hands provides a pointer to the true nature of the plantar lesion.

NEW TANK RESPIRATORS

IN patients with paralytic poliomyelitis the chief cause of dangerous respiratory insufficiency is paralysis of the intercostal muscles and/or the diaphragm. In such cases, provided that there is no paralysis of swallowing, treatment in a tank type of respirator is still the safest and most efficient method from the point of view of both the heart and the lungs. Formerly the patient began to receive artificial respiration only when he was in extremis, perhaps with widespread pulmonary collapse; but nowadays the vital capacity is commonly recorded at intervals of an hour or so while paralysis is spreading, and the respirator is used to rest weakening respiratory muscles long before serious embarrassment develops. It is essential, however, that tank respirators should incorporate modern improvements in design, and that those who use them should be well trained.

Improved types of tank respirator were developed quickly in the U.S.A. during the late war, but it is only in more recent years that improvements have been developed in this country. Some of these improvements are described in two papers, from Coventry and Bristol, published on earlier pages of this issue. These advances have depended on the work of many people, especially perhaps the members of the Breathing Machines Working Party of the Ministry of Health. Such a working party, however, has little authority to develop new apparatus, and it is noteworthy that these new machines have been developed without financial assistance from the Ministry.

In these respirators the first striking change is the "split front," which was first suggested by Bourdillon et al.¹ and was adopted by Messrs. Siebe Gorman.² A machine designed in Australia by Both incorporated a split of the whole cabinet and also of the rubber collar. Each of the new respirators is of this "crocodile" type, with which it is possible to dispense not only with the sliding stretcher but also with the difficult manoeuvre of pushing the patient's head through a hole in the front plate of the machine. Further, it has been found that the split rubber collar can be still airtight, and is both comfortable and easy to adjust to the neck contour. Another advantage of the crocodile type is the ease of full access to the patient and the freedom with which passive movements can be applied to the upper limbs: the tight shoulder-muscles commonly observed in respirator cases can thus be easily avoided. One danger of respirator treatment is that the patient tends to be nursed too much on his back; but these new models are adjustable over a wide range so that the lateral and semi-prone postures are feasible when the patient is handled by a skilled team.

There remains the question of how to provide positive-pressure breathing to the face when the cabinet is opened. The Bristol respirator incorporates the dome system used in some American makes and also by Christie and Esplen³; but the design is necessarily complex, and some will prefer Captain Smith-Clarke's simpler and much cheaper construction reported from Coventry by Dr. Galpine. Patients treated in this Coventry machine will depend on some other apparatus for positive-pressure breathing when the cabinet is opened, and Captain Smith-Clarke has designed a small bellows for this purpose which is operated by the main pump unit.⁴ The latest type of "Beaver" machine for positive-pressure breathing, approved by the Ministry of Health, or the pump designed by Russell and Schuster,⁵ can also

be used. In the absence of a dome, positive-pressure respiration can be maintained through a closely fitting face-mask or, better, through a mouth-piece of the type used with B.M.R. machines.

It is dangerous to use the tank type of respirator when there is paralysis of the pharynx as well as of respiration. In paralysis of this combined type, Lassen's method⁶ of positive-pressure breathing through a cuffed tracheotomy tube is probably the most likely to prevent fatal respiratory insufficiency.

OLD PEOPLE LIVING ALONE

SOLITARY old people, holding to their independence, are almost the only real poor left in this country; and their poverty makes heavy demands on their failing powers. Dr. Gordon Scott and Mrs. C. R. S. Williams,⁷ in a review of eleven North Oxfordshire villages, found that even in the relatively small population of 7500 there were at least 135 people aged sixty-five and over living alone. The survey was undertaken at the request of the Oxfordshire Association for the Care of Old People, which made a grant towards the cost. Mrs. Williams, who did the field work, visited 107 of the old people, of whom 79 were aged seventy-one or more. Broadly speaking, the older the people the less satisfactory were their home conditions: only 39 of the 107 had water inside the house; 56 of the remainder had a tap or well reasonably near the house; 11 had to go some distance for water, and 7 of these were aged seventy-six or more. The remaining old person got her water from the river. Only 75 of the 107 had electricity in their homes; 6 had gas; but 24 relied on lamps and 2 (aged over seventy-five) on candles.

Fuel is dear; and though 43 had been able to afford logs last winter to supplement their coal ration, 18 complained that they had been short of fuel and 26 spoke of the heavy expense. It seems possible that some kept themselves warm only by going short of food. Only those who were visiting the doctor could get medical certificates for extra fuel. Many found themselves in difficulties when it came to buying clothes or replacing household articles which were worn out: in general they had just enough for their day-to-day expenses with nothing over; 22 found it difficult to manage. Only 10 had any private means; 46 were receiving National Assistance, and as a result of the survey a further 5 were given it. At the time of the survey 24 were under treatment from their doctors, but 46 others complained of rheumatic pains, and 39 of sleeplessness—caused in most cases by pain. Some needed spectacles, or new spectacles; but of 19 in this situation, 11 were not physically fit to make the journey to have their eyes examined. Only 6 were very deaf, all of them over seventy, but they found it a serious handicap.

About a fifth had no visits from relations, and about a tenth had hardly any visitors at all. Health visitors seemed to call only on those who were using home helps. Most of the old people, however, were in touch with relations, either receiving visits from them, or going to stay with them from time to time. Many relied on good neighbours for help and friendship. Only 14 complained that loneliness was their biggest problem, and 50 said they had no special problems. They were nearly all greatly attached to their independence, and ready to bear much to retain it. In spite of narrow means and such inconveniences as an outside water-supply and no indoor sanitation, nearly all of them kept their homes in clean and shining order.

The impression is left of tremendous "gameness"—of a will to live and savour life. Dr. Scott believes that married couples on National Assistance are better off than those living singly, and suggests that an extension of the cheap milk scheme to old people living alone

would help to narrow the gap. He proposes also that local authorities, through their health visitors, should keep an eye on all old people over seventy living alone; and these, he thinks, should be able to claim a supplementary allowance of coal.

Might it not also be possible, surely, to improve their amenities in various inexpensive ways—by bringing an outside tap inside, for instance; by providing 'Elsan' closets indoors (if indoor sanitation is out of the question), and by sending a man to empty it at regular intervals; or by wiring for electric light, where this is available. Such things do not cost nearly so much to install as special bungalows cost to build; and they have the advantage of leaving the old person in surroundings to which he is accustomed, and which he often prefers.

PERIPHERAL AUTONOMIC NERVOUS SYSTEM

Meyling,¹ extending Leeuwe's work, has given his view of a new concept of peripheral autonomic innervation. This may be briefly summarised in two parts:

1. The viscera contain a peripheral nerve net composed of branching "autonomic interstitial cells" (A.I.C.). These are small ganglion cells; their processes form a syncytial network in which conduction is asynaptic and impulses are spread with a decrement. Like the larger autonomic ganglion cells these A.I.C. develop from neuroblasts. Neurofibrils are present in the A.I.C., and Nissl's granules can be stained; oxidases and peroxidases similar to those in sympathetic ganglion cells can be demonstrated. After section of the orthosympathetic and parasympathetic nerves, this network of A.I.C. retains its identity; thus in man the network will persist after section of the postganglionic fibres or after sympathetic ganglionectomy. The network innervates every effector cell—e.g., every smooth-muscle cell of the gut wall.

2. This A.I.C. nerve net is linked both to the efferent fibres of the orthosympathetic and parasympathetic systems and to the visceral afferent fibres. The individual efferent postganglionic fibres come to lie over portions of the all-pervasive A.I.C. network and, in their finest branches, form synaptic end-knobs or end-loops on the surface of the A.I.C. Afferent fibres in the same way have a synaptic connection with these A.I.C. This means that the A.I.C. network acts as a mediator between the nerve-fibres and the tissues.

The story of these "autonomic interstitial cells" goes back to Ramon y Cajal's description in 1894 of the "neurones sympathiques interstitiels" which he demonstrated by the Golgi method in the intestinal villi and elsewhere. Since then the nature of these cells has been disputed: some, with Boeke, Jabonera, and others, have regarded them as nervous; some, like Dogiel and Nonidez, have considered them connective-tissue elements; and some, like Lawrentjew and Schapadaesch, have thought them accessory nerve-cells of the lemnoblast (Schwann cell) type. Miss C. J. Hill, in her classical paper on the innervation of the intestinal wall, came to no conclusion about their nature.

The nature of the peripheral nerve net and of the termination of the postganglionic fibres has been variously pictured; some workers have denied the existence of any true syncytial network, while others have held that this exists but have disagreed on its character. Some have held that the final branchings of the postganglionic fibres end in a diffuse network, others that each postganglionic fibre ends discretely. All agree that orthosympathetic and parasympathetic fibres pass to smooth muscle in many of the viscera, but there is still little agreement on the nature of the terminal innervation of the smooth-muscle cells. Some of these differences are due to the difficulty of studying these fine structures.

Meyling's hypothesis, if accepted, will have very extensive implications. It may help towards the solution of the vexed questions of the nervous and humoral control of blood-vessels. It may also add to our understanding of the differences between the immediate and the late results of sympathectomy.

HOSPITAL BEDS FOR CHILDREN AN ESTIMATE OF NEEDS

Sir JAMES SPENCE
M.D. Durh.

MARY D. TAYLOR *
M.D. Durh.

*From the Department of Child Health, King's College,
Newcastle upon Tyne*

THERE is yet no formula by which the need for hospital beds can be accurately calculated. Other things being equal, the need should depend only on the incidence and type of illness in the town or district concerned. But other things are never equal. The customs of the people, the houses they live in, the habits of the doctors, and the quickness of the hospital staffs in dealing with their patients vary from place to place and from time to time.

Of all institutions where the sick are treated, the greatest variability of staffing, of method, and of custom is to be seen in children's wards and in children's hospitals. Nor is it only a matter of staffing, method, and custom. For example, some hospitals open children's wards, not to meet a clinical need, but to satisfy a nurse-training scheme or some other professional demand. These and other variable factors suggest to us that we should attempt the estimate of hospital beds for sick children that we offer here.

The Investigation

Our estimate is based on surveys that we made in 1943 and 1944, and which we repeated in 1950. The basis of the surveys was the child population in Newcastle upon Tyne in those years. From this total sample of about 50,000 children aged 0-12 years we identified each child who went to hospital or nursing-home. By personal examination of the records, the age of the child, the duration of the stay in hospital, and the nature of the illness were established; and duplicate admissions or transfer from one hospital to another were eliminated.

In our enumerations there was a possible source of error through some Newcastle children having been admitted to hospitals in other towns. The child away from home on holiday or at a boarding-school may have taken suddenly ill, or parents may have wished their child to be treated in another city. After examination of this possible source of error we conclude that its effects are so small that it does not materially affect our estimate.

The investigation took into account all children resident in the city under the age of 13 years, but in 1950 we extended it to include the children aged 13 years and 14 years. Ten hospitals and four nursing-homes were involved in one or both surveys, some of which were situated outside the city.

The standard of record-keeping in the hospitals was high, but their methods of classification of diseases were not sufficiently informative for our purpose; so we designed and used a classification and record which indicates more clearly than the traditional classification the type and scope of the work undertaken by the hospitals. We consulted the information collected by the Regional Hospital Board for the Ministry of Health on their S.H.3 return, but this was of no value to us.

LOCAL FACTORS

In interpreting the results we would ask the reader to keep in mind certain factors favouring an economical use

* Holding a research grant from the Scientific and Research Committee of the Newcastle Regional Hospital Board.

of beds in Newcastle, which might not obtain some other places.

(1) The hospital accommodation for children was ample, and there was no waiting-list for admission, except for tonsillectomy and operation for squint.

(2) The threshold of admission to hospital was high, because of the prevailing hospital policy that whenever possible the sick child should be treated at home.

(3) This policy was reinforced by the provision of a daily outpatient consultation service to which the family doctors could refer their patients immediately. Conducted by senior and experienced consultants, this service reduced the demand for beds.

(4) The children were admitted mainly to children's hospitals or children's departments arranged and staffed as combined clinical units, in which personal consultations between paediatric physicians, surgeons, and specialists were so promptly obtained that time and anxiety were saved.

(5) In these children's hospitals and departments all children were examined by an experienced paediatric resident at the time of admission to hospital, and the allocation of patients in wards and beds was under his control with consultant advice immediately available. These measures eliminated outbreaks of those infective illnesses for which children's wards are often closed, and in other ways contributed to a full and efficient use of bed accommodation throughout the periods of survey.

(6) In two hospitals time was saved by using, for the nursing of sick children, the Babies' Hospital method of "mother-nursing" which shortens the child's length of stay in hospital.

(7) Newcastle being a regional and university city, its hospitals are self-sufficient in their consultant and specialist services. Therefore the estimates we make are for similar cities. For those towns and districts which are not self-sufficient in paediatric and specialist services, and from which transfer of cases to a regional centre will take place, a reduction in the estimate is required.

(8) If our estimates are to be used for policy and plans in the future, the changing trends of mortality must be noted. The disappearance of diphtheria (185 admitted in 1943, and 0 in 1950), the diminished hospital needs for scarlet fever (495 in 1943 and 26 in 1950), are on the credit side. On the debit side is the long stay in hospital for modern forms of treatment of children with tuberculous meningitis; but it can be predicted that after about ten years there will be a steady reduction in the number of children coming to hospital for treatment of tuberculosis. On the debit side also is the increase in tonsillectomy, but it is within the bounds of possibility that a changing attitude towards this operation will diminish greatly the demand that it shall be done.

(9) A local policy about scarlet fever exercises a paramount influence on the need for hospital beds. In Newcastle the policy, which we hold to be the right policy, is to admit to hospital only those children with scarlet fever, the severity of whose illness indicates the need for hospital treatment. In some other towns all cases of scarlet fever are admitted to hospital, however mild the illness may be.

THE POPULATION

Estimates can be based on (a) the total population (table I), or (b) the population of the age-groups under

TABLE I—POPULATION OF NEWCASTLE

	Total	Children
1943	254,800	49,800 under age of 13
1944	262,920	50,400 " " " 13
1950	294,800	{ 57,800 " " " 13 66,130 " " " 15

TABLE II—ANNUAL BIRTHS AND BIRTH-RATE

	Live annual births	Newcastle birth-rate	National birth-rate
1943	4548	17.8	16.5
1944	5359	20.4	17.6
1950	5051	17.14	15.8

TABLE III—ANNUAL ADMISSIONS IN AGE-GROUP 0-12 YEARS

—	Total	For tonsillectomy	For scarlet fever
1943 } 1944 }	3743	890	495
1950	3980	1482	26

study (table I), or (c) the birth-rate (table II). Our final estimates are based on the first of these and are expressed as rate per 100,000 of total population. This is probably the best method of comparing one town with another, but for strict comparison the governing factor of birth-rates should also be considered.

The Findings

There is so little variation between the years of 1943 (3782 admissions) and 1944 (3704 admissions), that the

TABLE IV—ANNUAL ADMISSIONS IN AGE-GROUPS

—	Infants (0-12 mos.)	1-4 yr.	5-12 yr.	13-14 yr.	Total
1943 } 1944 }	419	1293	2031	(not counted)	3743
1950	449	1197	2334	260	4240

figures for these two years are dealt with as an annual average of 3743 children (aged 0-12 years) admitted to hospital in each year, which is 7.48% of the childhood population in that age-group, or 1410 per 100,000 of the total population. In 1950, 3980 children aged 0-12 years were admitted, which is 6.85% of children in that age-group, or 1350 per 100,000 of the total population. In 1950 there were in addition 260 children aged 13 or 14 admitted to hospitals. These figures show that 1 child in 15 is admitted to hospital each year, which is equivalent to every child being admitted to hospital once before the age of 15.

The admissions for tonsillectomy and scarlet fever may play so large a part in the figures that they must be considered separately. In the years 1943 and 1944 the average annual admission for tonsillectomy was 890, and in 1950 it was 1482. For scarlet fever the numbers were 495 in 1943 and 1944, and 26 in 1950 (table III).

An analysis of admissions is given in tables IV and V, and we recommend that annual reports of children in hospital should be presented in this way and extended so that each category of illness is related to age-groups, to length of stay, and to results. This information is necessary if the type of clinical work in hospitals is to be judged.

The ages of children (table IV) are grouped in these three categories: (1) infants (aged 0-12 months); (2) pre-school children (aged 1-4 years); and (3) school-children (aged 5-12 or 5-14 years).

Our estimate of the lengths of stay, which we use later, were made from the following groups: (1) for a period of less than a month; (2) for one to two months; (3) for two or three months; and (4) for three months or more.

Calculation of Bed Requirements

For Tonsillectomy

In 1943 and 1944 there were 890 annual admissions of children to hospital for tonsillectomy. In 1950 there were 1482 up to the age of 12, and, 1574 up to the age of 14. The 1950 figure represents a higher-than-normal level when waiting-lists were being worked off. As an estimate for the future we will take a figure of 1200 tonsillectomies a year in children up to the age of 12 years, and 1250 up to the age of 14 years. This represents 1.8% each year of the child population at risk, and 24.7% of the annual births. Assuming that each child spends

either two or three days in hospital and that each bed used for this purpose accommodated 2 patients a week, 12 hospital beds would suffice for these 1200-1250 children admitted for tonsillectomy—i.e., 4 beds per 100,000 of the population.

Length of Stay

A distinction must first be made between the admissions to "acute" hospitals and the admission to "long-stay" hospitals, or children's sanatoria; but the latter form so small a part of the whole (30 admissions in 1943 and 88 in 1950), that we will confine our estimate of long-stay beds for children to the statement that about 35-45 will be required for a population of 300,000, or 12-15 per 100,000 of the population, assuming that the average stay in that kind of hospital is six months; but this estimate will vary according to the clinical policy of the hospitals, and its adjustment to the wishes and capabilities of the parents. This estimate of long-stay beds may be on the high side.

For all other categories of illness (i.e., excluding tonsillectomy and long-stay illnesses in special hospitals, for which we have already made a length-of-stay estimate) we have calculated an average length of stay expressed as the number of children per bed per year, by analysing the records of three fully staffed and active children's departments or hospitals, which admit about 4000 children a year with all types of medical, surgical, and special illnesses. A few of them (40 in the year) were in the wards for more than three months, and 150 for one to three months, but these were included in our calculation of the "average length of stay."

The average length of stay (excluding those in hospital for tonsillectomy) was just over fourteen days. From this we estimate that each hospital bed would accommo-

date 23 patients a year, making due allowance for turnover and other adjustments.

In 1950 for the Newcastle children in the age-group 0-12 years there were 2410 admissions for illnesses in this category of medical, surgical, and special diseases. According to our estimate, 105 beds would be required for these. Adding the group of children aged 13-14 years, 110 beds would be required.

Final Estimate

Assuming that existing conditions continue, Newcastle, with its population of 295,000, including 66,130 children in the age-group 0-14 years, will require—for all types of illness other than those admitted to sanatoria or similar long-stay hospitals—the following number of hospital beds:

For tonsillectomy	12
For other illnesses	110
Total	122

In other terms this is 42 beds for children aged 0-14 years, per 100,000 of the total population. In addition we have tentatively suggested that 12-15 beds per 100,000 of the population would be required for long-stay cases in special hospitals.

Final Comment

This estimate of 42 children's hospital beds per 100,000 of the population is for an industrial town in the North of England with a high birth-rate and a high morbidity incidence. It is a tight estimate: to be on the safe side, the figure should be set at 50 per 100,000. On the other hand, fewer beds would be needed in some other towns, and considerably fewer in those districts or towns which are not self-sufficient in specialist and pædiatric staffs.

This number of beds suffices for all hospital treatment of children, other than for what goes on in sanatoria and maternity hospitals.

In a university town which is a teaching and specialist centre still more beds will be required to meet regional needs.

This estimate may serve as a guide to the use of beds. We have found that hospital beds for children are used more effectively—i.e., with a higher turnover in numbers—and with greater satisfaction to patients, to parents, and to staff, if the children's wards are grouped and arranged together in children's departments or hospitals, of convenient size, which bring the medical, surgical, and specialist staff into a close and unavoidable working relationship. This way works better than scattering children's beds in specialist departments.

While our estimate may serve as a numerical guide, it cannot be used to judge the quality or value of clinical work, or the relationship of staffs and the arrangement of their responsibilities, on which so much depends in children's wards. The worth of these is measured, not by time-motion studies or by enumeration, but by the judgment of those who are fit to judge.

ESTIMATES FOR 1954-55

THE National Health Service estimates for 1954-55¹ allow for gross expenditure in England, Wales, and Scotland totalling £504,789,835, compared with £489,771,648 in the past year. Appropriations-in-aid (including contributions from the National Insurance Fund) are estimated at £71,656,350, compared with £70,094,770; and thus the net cost is £433,133,485, compared with £419,676,878—an increase of £13,456,607. The gross totals, which include grants for Civil Defence services, are made up as follows:

	1954-55 (£)	1953-54 (£)
Hospital, specialist, and ancillary services	321,492,525	310,511,603
General medical, dental, pharmaceutical, and supplementary ophthalmic services	140,296,000	135,215,520
Grants to local health authorities	23,198,010	21,558,020
Training services, &c.	1,695,200	1,689,750
Broadmoor Institution and mental-deficiency hospitals	1,498,200	1,504,000
Liabilities arising from establishment of N.H.S.	5,753,500	6,435,030
Superannuation	7,391,500	6,162,500
Civil Defence services	2,675,200	5,926,315
Other services	789,700	769,010
	£504,789,835	£489,771,648

Capital expenditure by hospital boards is estimated at £12,300,000 in 1954-55, compared with £9,975,000 in 1953-54 (an increase of £2,325,000), and maintenance expenditure at £295,820,000, compared with £287,496,558 (an increase of £8,323,442).

The grant-in-aid to the Medical Research Council¹ is put at £1,947,109 in 1954-55, compared with £1,805,856 in 1953-54. Of the total, £102,428 is for building. The grant for general expenses (amounting to £1,844,681 after deduction of £115,509 in receipts) is compounded as follows: administration, £68,532; provision for general scientific purposes, £18,400; National Institute for Medical Research, £386,187; research units and external scientific staff, £1,142,131; special grants to institutions, &c., £177,340; temporary research grants and training awards, £197,600.

Public Health

DOES INFLUENZA SPREAD WITHIN THE HOUSEHOLD?

R. E. HOPE SIMPSON
M.R.C.S.

DIRECTOR, EPIDEMIOLOGICAL RESEARCH UNIT (PUBLIC HEALTH LABORATORY SERVICE), CIRENCESTER, GLOS

IAN SUTHERLAND *
M.A. Camb., D.Phil. Oxf

MEMBER, STATISTICAL RESEARCH UNIT, MEDICAL RESEARCH COUNCIL

THERE is nowadays a general belief that influenza is spread by direct transmission of the causal organism from person to person. Less than a century ago, however, most of the careful students of the disease dismissed this explanation of influenza epidemics because it did not agree with their experience of the behaviour of the disease. Hirsch (1883), in a fine survey of the then available information, said:

"... there is not the slightest cogent reason for supposing that the several parts of an influenza pandemic stand in a genetic relation to one another, or that it is a question of the conveyance of a disease-producing substance from place to place.

"... The question whether influenza is *communicable* or *contagious* has given occasion to a lively controversy. In more recent times the great majority of observers have answered it decidedly in the negative, not so much on the strength of the many single observations which tell against the communicability of the disease, as on the ground that the spread of influenza can be shown to have taken place quite independently of intercourse. To this argument I may add the fact that it has not spread more quickly in our own times, with their multiplied and perfected ways and means of communication, than in former decades or centuries."

The transformation of medical opinion began in 1892 when Pfeiffer described *Haemophilus influenzae*, and the

* Working at the Institute of Social Medicine, Oxford for much of the time during which this paper was in preparation.

outstanding epidemiological problems began to be less clearly visible in the cloud of controversy about the validity of the claim that Pfeiffer's bacillus was the causal organism of influenza. Just over forty years later the ætiological problem seemed to be settled by Smith, Andrewes, and Laidlaw (1933) who

(1) Transmitted the disease to ferrets by intranasal instillation of filtered nasal washings from a human case of epidemic influenza.

(2) Transmitted the disease from ferret to ferret both by natural contact and by intranasal instillation of filtered material.

The ensuing spate of research on viruses has established that epidemics of clinical influenza are usually associated with the presence of one or more of the group of influenza viruses, and there seems good reason to suppose that these organisms cause the disease. But this important knowledge by itself advances us little in unravelling the complex reasons for the appearance and disappearance of influenza epidemics.

The time is ripe for an assessment of the epidemiology of influenza against the background of the bacteriological and virological knowledge which has accrued during the last sixty years. Is it now possible to adduce statistical evidence that influenza is spread directly from person to person? The present paper examines the pattern of the disease in households during a recent epidemic.

Investigation

The data were collected during the influenza epidemic of 1951 in a general practice in and around Cirencester. Owing to the considerable burden of work some desirable statistics were omitted. For example, those concerning the extent of the epidemic in the practice as a whole and the proportion of households which escaped attack. However, a close watch was kept on 100 households in which at least 1 case of influenza was known to have occurred; the households were not otherwise subject to any conscious selection. The sex and age of each member of these households were recorded, with the date of onset and the "worst" day for those who contracted the disease. The material analysed below is very slightly different from that given in a provisional report (Hope Simpson 1951).

An element of uncertainty always attaches to the clinical diagnosis of influenza. All the cases upon which this study is based occurred during an epidemic of influenza, the symptoms were similar to those reported from other parts of the country, and of 69 paired samples of sera taken during the epidemic (although not all from these households) more than 80% were positive for influenza virus A. It therefore seems likely that most of the recorded cases were true influenza but that an unknown proportion were other diseases; also some atypical cases of influenza may have been diagnosed as other conditions.

The 100 households contained 385 individuals. Since the basis for selecting a household was the occurrence of a case of influenza, 100 of these individuals represented first cases in the household. (In a few households the first 2 cases started on the same day, and 1 was chosen at random as the "first" case.) Of the other 285 individuals, 223 (78%) subsequently manifested

influenza within fifty days of the first case in the household. Two women and a man, all aged over 75, died of the disease. In the ensuing analysis the 385 individuals are studied first, and then the 100 households.

SEX AND AGE

It was shown by Hope Simpson (1951) that the individuals in the affected households had a similar age-distribution to those in the practice as a whole. The same applies to the proportions of the sexes in the sample and in the practice. Thus there is nothing about the age and sex of the people in affected households to distinguish them from other people in the practice.

Within these households the individuals fall naturally into three groups: the first cases, the subsequent cases, and those who escaped. These three groups are compared in table I as regards sex and in table II as regards age. There appears to be a slight preponderance of males among the first cases, but this may be no more than a chance fluctuation; that is to say, there is no real evidence that one sex or age-group was more likely than another to manifest the first case of the disease in the household, nor, when the disease was present, that one sex or age-group was affected more than another. Further, since less than a quarter of those exposed to influenza in the household escaped, the level of immunity was low. There is no evidence that immunity was related to sex or age.

Influenza thus seems to have attacked male and female, old and young, indiscriminately. The figures offer no evidence about possible lines of the spread of the disease in the way that the data on measles (Hope Simpson 1951) and the common cold (Lidwell and Sommerville 1951) indicate the rôle of the school-child in introducing the disease into the household.

SIZE OF HOUSEHOLD

The 100 households ranged in size from 2 to 11 persons. Table III shows the numbers of first and subsequent cases

TABLE II—INFLUENZA AMONG 385 PERSONS IN 100 HOUSEHOLDS BY AGE (YEARS)

	Less than 15	15-24	25-44	45-64	65 or more	Total
First cases	22 (22%)	10 (10%)	34 (34%)	23 (23%)	11 (11%)	100
Subsequent cases	60 (27%)	29 (13%)	74 (33%)	42 (19%)	18 (8%)	223
Escaped	9 (15%)	9 (15%)	24 (39%)	15 (24%)	5 (8%)	62
Total	91 (24%)	48 (12%)	132 (34%)	80 (21%)	34 (9%)	385

$$\chi^2 = 6.67 \text{ with 8 d.f. } 0.70 > P > 0.50.$$

and of those who escaped, according to the size of the household. The final column shows the percentage of those exposed to risk who were subsequently attacked. The percentage is least for households of 4 (in which 3 persons were exposed to the risk of subsequent attack) and rises for smaller and larger households. This apparent association between size of household and subsequent attack-rate just attains statistical significance at the 5% level, and so warrants further investigation.

NUMBER OF SUBSEQUENT CASES

Methods

Certain widespread diseases, such as measles, chicken-pox, mumps, and smallpox, have epidemiological features which are characteristic of direct person-to-person spread of the disease. In continuing this investigation of influenza it is useful to analyse the behaviour of one of these diseases—namely, measles—side by side with that of influenza, so as to compare their epidemiological features more closely.

The data on measles were collected, in the same area as those on influenza, in a series of epidemics from

Jan. 1, 1947, until March 31, 1952. All known cases in each outbreak have been included. The sex and age of each "susceptible" member of affected households were recorded, with the date of fullest development of rash for those who contracted the disease. A "susceptible" member was someone who gave no history of previous attack.

For the investigation of the number of subsequent cases of influenza the household is taken as the unit of study and is characterised by the number of persons in it and the number of cases of influenza which occurred after the first case. For measles the household is characterised by the number of susceptible members aged under 15 years, and the number of cases of measles which occurred among them after the first case. Tables iv and v give the basic data in this form.

Apart from the possibility of fresh introductions of a disease into a household, there are two main ways in which subsequent cases of that disease could arise :

(1) All members of the household are exposed to the risk of contracting the disease, but the agent does not spread directly from person to person. An example of this class of

TABLE III—INFLUENZA AMONG 385 PERSONS IN 100 HOUSEHOLDS BY SIZE OF HOUSEHOLD

No. of persons in household	First cases (i.e., no. of households)	Subsequent cases	Escaped	Percentage subsequently attacked
2	20	18	2	90
3	26	38	14	73
4	24	51	21	71
5	18	54	18	75
6	9	39	6	87
8	2	13	1	96
11	1	10	0	
Total	100	223	62	78

For differences between subsequent cases and those who escaped $\chi^2 = 11.46$ with 5 d.f. $0.05 > P > 0.02$.

disease would be typhoid fever from a well serving several households, where the subsequent hygienic precautions were sufficient to prevent secondary cases arising from infected clothing and excreta. Another example would be an illness caused by an organism which lay dormant in each person but recrudesced from time to time in response to suitable stimuli affecting several households.

(2) The second way in which subsequent cases could arise is by spread of the disease from person to person within the household, as in measles. The distinction is essentially between a disease which is not spread directly from person to person (class 1) and one which is (class 2).

For each of these two classes of diseases it is possible (with certain assumptions specified below) to make a theoretical prediction of the proportion of households of a certain size in which 0, 1, 2, &c., subsequent cases occur. If these predictions are compared with the pattern

TABLE IV—ACTUAL AND EXPECTED NUMBERS OF HOUSEHOLDS OF 3-5 PERSONS ACCORDING TO NUMBER OF SUBSEQUENT CASES OF INFLUENZA

observed for particular diseases—in this instance influenza and measles—it may help us to decide whether the causal agent is being transmitted directly from person to person. For a disease in class 1 an appropriate theoretical model to try is a simple binomial distribution. For a disease which spreads directly from one person to another (class 2) an appropriate model to try is a chain of binomials (Greenwood 1931).

Results of Analysis

The results of the calculations for the simple binomial and the chain binomial are given in tables iv and v. The principal difference between them is that, for a given size of household, the chain binomial yields larger expected values than the simple binomial when few or many subsequent cases occur. It seems, although the data are scanty, that the chain binomial fits the observed pattern better than the simple binomial for influenza households of 4 or 5, whereas the position is reversed for households of 3. For measles households of 3 or 4 the chain binomial also fits much better than the simple binomial. Households of 2 are not included in the table, because the chain binomial and the simple binomial predictions are identical for these households.

The effect of fresh introductions of the disease into households may be referred to briefly. In the absence of evidence to the contrary it is assumed that they did not occur very often. The effect of a few such introductions would be to increase the average number of subsequent cases. Apart from this increase the form of a simple binomial distribution would remain unchanged. The effect on a chain binomial is not quite so plain, but this distribution is unlikely to be seriously deformed. In other words, in drawing conclusions from tables iv and v, any fresh introductions of influenza or measles into the households may be ignored. There are, however, other reasons why it may not be valid to apply these two formulae to the data.

Applicability of the Simple Binomial

The simple binomial is an appropriate model for diseases of class 1 only if the risk of a subsequent case of the disease is uniform throughout all the households of a given size. It has already been shown that the incidence of influenza in the epidemic as a whole did not vary appreciably with sex or with age, and the mortality from influenza does not appear to be affected by social status (Registrar-General 1938). We have thus no evidence against the applicability of the simple binomial to influenza. Measles is referred to below.

Applicability of Chain Binomial

The chain binomial in its simplest form rests upon two assumptions: (1) each person without the disease runs the same risk of being infected by the first case as by any subsequent cases; and (2), as for the simple binomial, the risk is uniform throughout all households of a given

size. In the original application of the theory Greenwood (1931) found that the chain binomial agreed satisfactorily with data on measles in the form of our table v, whereas the simple binomial did not. This was confirmed by Wilson et al. (1939), but by a more detailed analysis they showed that the agreement was no more than fortuitous. In fact the first of the two assumptions, that each person without the disease runs the same risk of being infected by the first case as by any subsequent cases, was untenable. Those exposed to the first case of measles were substantially more likely to succumb than those exposed to subsequent cases.

In a further analysis Greenwood (1949) showed that the second assumption, that the risk is uniform throughout all households of a given size, was also untenable. The risk that an individual would catch measles from a home contact varied from one household to another of the same size.

As regards influenza, the uniform incidence with sex and age suggests that the second assumption may not be unrealistic, and that in influenza the risk may be uniform throughout households of a given size; but it is arguable that the first assumption—that the risk is equal for each of the persons in the household—is unlikely to hold for any disease if it is transmitted directly from person to person. The secondary cases, which are infected by the first case, will tend to include the members of the household who have the least individual resistance. Accordingly, those who remain uninfected will less readily fall victims to the secondary cases, and so on. No direct check can be made to see whether this is happening with influenza, since, unlike measles, the cases do not obviously group themselves in "generations." In fact, if they did so, we should not be trying to obtain evidence about the infectiousness of influenza in so tortuous a fashion.

Discussion

We are thus left in some uncertainty whether the satisfactory fit of the chain binomial to the influenza data in the larger households is fortuitous or whether it is real evidence in favour of the direct spread of the disease from person to person. On the other hand, the failure of the simple binomial in these households encourages us to reject the hypothesis that influenza is not infectious.

Before considering the different pattern presented by influenza in the small households it is desirable to recall an earlier finding. Other influences excepted, a consequence of the simple binomial theory is that the subsequent attack-rate is independent of the size of the household. Similarly, a consequence of the chain binomial is an increase in subsequent attack-rate with increase in size of household. The figures in table III suggest that neither of these patterns represents the whole truth for influenza. Thus, even if we can accept one of these two theories as a description of the method of spread of influenza within a household, it becomes necessary to examine other influences which may affect to a different extent households of different sizes.

Most people would prefer the explanation that influenza is infectious to the possibility that it is not. But in relation to our evidence this raises two difficulties: (1) the failure of the chain binomial to fit the data for households of 3 (there are too many instances where only 1 of the 2 persons at risk were attacked); and (2) the high subsequent attack-rate in households of 2. In the present sample most of the households of 2 consist of a married couple. The explanation might be that there is an inherently greater risk of one partner in a marriage infecting the other than of either infecting any other member of the household. If this were so it would help to account not only for the high subsequent attack-rate in households of 2 but also for the preponderance of households of 3 in which only 1 of the 2 persons at risk was attacked. In larger households the

effect might be less noticeable because of the larger numbers at risk. There is another possibility: the doctor may have been called more readily to a household of 2 when both members were incapacitated by influenza than if only 1 was. A bias of this kind would lead to a spuriously high subsequent attack-rate in the chosen sample of households of this size.

And there this approach to the problem must be left. We have gone as far as, perhaps further than, the available information warrants. For progress on these lines considerably more data are required.

INTERVAL BETWEEN CASES

So far, all the analyses have been devoted to the frequency of occurrence of subsequent cases and none to their timing. For many infectious diseases—e.g., measles, chickenpox, and infective hepatitis—there is a reasonably constant serial interval between the infecting and the infected cases. This interval represents the duration of the reproductive cycle of the causal organism (Hope Simpson 1952) and will show itself only if the duration of infectiousness of the first case is short, and if the incubation period does not vary too widely. If it is possible to uncover a serial interval between cases of influenza in the same household it will show that the disease is passing directly from person to person, and at the same time determine the duration of the reproductive cycle of the causal organism. Failure to uncover the interval may be due either to the fact that the disease does not spread directly from person to person, or to the other factors indicated above.

Evidence from Households with 3 or more Cases

Methods for studying intervals between cases were investigated by Greenwood (1946), who envisaged the use of data on separate households like the present material. The approach adopted here is to enumerate the intervals between successive cases according to their duration, in households with 3 or more cases, and to compare them with what would be expected if the timing of the cases between the first and the last were purely random. The relevant theory is sketched by Greenwood (1946) on pp. 100-101 of his paper. For influenza the intervals between the dates of onset and those between the "worst" days of the disease were enumerated separately, since one might give a more precise indication of any serial interval than the other. There were certain gaps in the information, particularly for "worst" days. The duration of 171 intervals between dates of onset and of 134 between "worst" days could be determined. For measles the intervals between the days of fullest appearance of the rash were enumerated. The duration of 151 intervals could be determined.

If there is a chain of infection, which is indicated by a serial interval, there will also be instances where 2 or

TABLE VI—COMPARISON OF ACTUAL AND EXPECTED INTERVALS BETWEEN SUCCESSIVE CASES OF INFLUENZA IN SAME HOUSEHOLD

Duration of interval (days)	Interval measured between

χ^2 with 13 d.f. = 36.65.

$P < 0.001$.

more cases are infected by a single earlier one, and these will tend to occur close together in time. Thus in addition to a preponderance of intervals corresponding approximately to the serial interval there would be an excess of very short intervals. Any fresh introduction of the disease into the household might blur, but should not completely obscure, these tendencies. The comparisons of the actual intervals with those expected from a random distribution of cases are given in tables VI and VII. For influenza the intervals between dates of onset show no important deviations from the random pattern. There is a preponderance of intervals of one or two days between the "worst" days of successive cases, but this cannot be regarded as being of any aetiological importance, because the deviations are within chance limits, as the χ^2 -test shows. On the other hand, the analysis for measles shows a definite serial interval.

This examination of intervals therefore gives no evidence how influenza may be transmitted within the household. If it is passing directly from person to person, there must be considerable variability in the length of the incubation period, or each person must remain infectious for a period which is comparable in length with the incubation period; or, of course, both of these factors may apply.

Evidence from Timing of Influenza Cases in Household compared with that in the Whole Epidemic

The timing of the influenza cases may be examined in another way. If there is no connection between the cases which occur in a household, their distribution in time might reflect the time scatter in the epidemic as a whole, or in this sample of it. Statistically the point can be tested quite simply by an analysis of variance, which shows beyond reasonable doubt that the cases within a household tend to occur closer together in time than would be expected from the scatter of all the cases studied. (The ratio of the variance estimate between households to that within households is 3.11, with 89 and 219 degrees of freedom, for the dates of onset, and 2.82, with 89 and 199 degrees of freedom, for the worst days of the disease. Each chance probability is less than 0.001. Some cases were omitted from the analysis because one or other of the requisite dates were unknown.)

Although this analysis demonstrates some connection between the cases of influenza which occur within a household, it gives no indication of what that connection may be. A process of infection within the household is by no means the only possibility. The finding may be alternatively expressed by saying that the members of one household tend to be afflicted at a different stage of the epidemic from members of another; a disease spread by contaminated food or drink, by an insect, or by

some other vector might well reach different households at different times and present just the same picture.

Discussion

Does the mechanism of person-to-person spread explain what is known about the epidemiology of influenza? Of the large number of facts which need explanation the most salient and difficult are probably these—that influenza may come as an epidemic or a pandemic in two successive years or even more often, or it may disappear for twenty or thirty years or more; and that when it returns, after either a short or a long interval, it attacks with a high rate irrespective of age and apparently irrespective of previous attacks.

This is indeed a puzzling picture. If we postulate a lack of immunising properties, why do epidemics disappear at all? If numerous different strains of virus are responsible which give little or no cross-immunity—i.e., if there are numerous different diseases all more or less identical clinically—why do epidemics disappear for such a long time; and, having thus been absent, why do they ever reappear? If the sudden appearance of a mutant is responsible for the great outbreaks it should very soon become apparent to the laboratories. But where in the meantime are the parent strains lurking?

In the face of so many perplexities about this important disease there is urgent need for more precise information about the extent and distribution according to age, sex, previous attacks, and geography of each outbreak. Diagnostic difficulties are formidable for the field worker, even with facilities for virus studies. It seems, nevertheless, that this is the only way in which the problems can be solved; even imperfect attempts may supply evidence and experience, pointing the way to more successful studies.

In view of the clear-cut results with some other diseases it seemed reasonable to look for evidence of direct transmission in careful family studies of influenza. In the present study there is a vivid contrast between the clarity of the answer for measles and the equivocal results for influenza; yet if influenza is spread directly from person to person it must be at least as infectious as measles. This makes the lack of clear evidence all the more remarkable. The fit of the prediction by the chain binomial with the actual experience in the larger families suggests that influenza may be spreading from person to person inside the family; but, if this is actually happening, how can we explain the lack of a secondary wave of cases, such as occurs with measles and other diseases in which direct person-to-person spread is certain? One explanation would be that a large number of the cases included were not in fact influenza. Or it may be that the incubation period in influenza varies widely, or that the period of infectivity is of similar duration to the incubation period. Such factors could easily obscure the evidence of direct spread.

Then again the evidence provided by family studies depends on the family acting as a self-contained community transmitting the disease more readily than the community as a whole, with the result that entries into the family from outside after the first case tend to be relatively rare events. Perhaps influenza is so highly infectious that the family ought not to be treated as a community separated from the general community, because entries from outside happen with such ease that cases subsequent to the first case in the family are often re-entries. This is unlikely to be the complete explanation, because many of the intervals between subsequent cases in families were long; hence the opportunity of catching a disease as infectious as influenza inside the family would have been greater than waiting for a re-entry from outside. The more infectious the disease the more likely it seems that the picture inside the family would

be of a first case among susceptibles, followed by a generation including the majority of susceptibles at risk, and that is not found in influenza. In measles, for example, more than 70% of the susceptibles at risk in the family take the disease at the first opportunity (Hope Simpson 1952).

These points being taken into consideration, there seem to be two alternative explanations :

(1) Influenza is transmitted directly from person to person, but this feature is unrecognisable in family studies as a result of factors such as a widely variable incubation period, or a period of infectivity of similar duration to the incubation period, or a combination of them.

(2) Influenza epidemics do not depend on the mechanism of direct person-to-person spread.

The problem cannot be settled with the material that we have studied here. In any future epidemic it would be profitable to collect in addition data for households selected at random and to compare them with data for households selected because they have at least 1 case of influenza.

Summary and Conclusions

In an attempt to decide whether influenza is spread directly from person to person the pattern of influenza during the 1951 epidemic was studied in 100 households which experienced at least 1 case of the disease. The households contained 385 persons.

Influenza appeared to attack males and females, old and young, indiscriminately. The attack-rate among those exposed to the first case in the household was 90% for households of 2, dropped to a minimum of 71% for households of 4, and thereafter rose with increasing size of household.

The distribution of multiple attacks in households with 4 or 5 members was more nearly in conformity with that to be expected from a direct spread of the disease from person to person than with a hypothesis which precluded this method of transmission. Suggestions are made which might explain certain anomalies in households with 2 or 3 members.

Within each household the cases of influenza tended to occur at the same stage of the epidemic. This does not necessarily mean that influenza is spread by personal contact in the household.

No evidence could be found of any serial interval between successive cases of the disease within the same household.

The experience in households with cases of measles was analysed for comparison with that in the influenza households. It shows clear evidence of direct person-to-person transmission of measles.

The data available here are tantalisingly scanty. Much could be learnt from a larger study on similar lines of influenza as well as of other diseases.

We wish to express our appreciation of the late Dr. W. T. Russell's interest in this study and his early work upon the records. Miss Janet Edmonds and Miss Joyce Dawson, of the Epidemiological Research Unit staff, put in a great deal of painstaking work to ensure that the records were as complete and accurate as possible. We should also like to thank the sick families for their patient and helpful coöperation.

Mr. Bevan on "A Municipal Hospital Service"

The *Municipal Journal* asked Mr. Aneurin Bevan, as the Minister responsible for the creation of the National Health Service, to discuss their suggestion that hospitals should be transferred to local government.¹ In his reply Mr. Bevan² admits his regret that in framing the health service he was unable to make more use of local-government machinery. But not even the larger local authorities are big enough to carry some medical specialties; nor could facilities for treatment be allowed to vary according to local finances, and national financial responsibility conflicts with local government administrative responsibility. Though he believes that it is a defect of the N.H.S. that the administrative agents are selected by the Minister instead of being elected by the people, he recognises that it is inevitable until the present units of local government are fundamentally revised.

True local government, he holds, must be "so near to the people as to ignite and keep their interest." The present borough and district councils are too small for efficiency and the administrative counties too large for democracy to flourish. In his view the ideal set up would be some 240 authorities, most of them covering a population of about 75,000. Except in the big towns, each should include rural as well as urban areas. They should be all-purpose authorities with a diversity of important functions sufficient to attract the best kind of councillor and large enough to command efficient teams of officers.

Local authorities of this standing could, he believes, appropriately assume responsibility for the administration of the hospitals as agents of the Minister. They would make all staff appointments except specialists—who would be appointed on the recommendation of a regional advisory body. But Mr. Bevan is firm that no local finances should be levied, for this would destroy the unity of the service. He also stipulates that local authorities should make full use of voluntary workers, otherwise he foresees that power may merely be transferred from "offices in Whitehall to those in the town hall." He believes that now the fears of the doctors have been largely assuaged they would be more disposed to "set aside the traditional antagonism between the clinicians and the medical officers of health."

Report on Detergents

In May last year the Minister of Housing and Local Government appointed a committee, with Sir Harry Jephcott, M.Sc., as chairman, "to examine and report on the effects of the increasing use of synthetic detergents and to make any recommendations that seem desirable with particular reference to the functioning of the public health services." This was a heavy assignment and the committee still have much work to do, but so many people are keenly interested in the subject that an interim report³ has been published.

There are four reasons why people have been worried about detergents: they may cause dermatitis and have other dangers to health; they may cause corrosion of domestic equipment and plumbing; there have been reports of excessive foaming at a number of sewage works; and foam on the rivers into which sewage effluents are discharged has given rise to concern for the purity of the river water. On these questions, the committee have collected evidence from many sources. Both synthetic detergents and soap-powders can cause dermatitis in certain cases, but there has been no significant increase, the report says, in this complaint since synthetic detergents came into common use. The committee's advice to housewives is: choose the detergent that suits you best; do not use more than you need; and always rinse and dry the hands thoroughly afterwards. The possibility that traces of detergent may

1. See *Lancet*, March 13, 1954, p. 568.

2. *Municipal Journal*, March 12, 1954, p. 544.

3. Interim Report of the Committee on Synthetic Detergents. H.M. Stationery Office. Pp. 7. 4d.

be ingested from crockery and in other ways is being examined, but there is so far no evidence that ill effects may be caused by this means. The committee do not think that corrosion will lead to widespread difficulties, particularly if sinks are well rinsed after each washing.

The most serious problem is the effect of detergents on sewage treatment and the disposal of effluents. A number of methods for suppressing foam formation at sewage works have been tried with some success—notably in the U.S.A. But further research is necessary before any one method can be recommended for general use in this country. Meanwhile, foaming is not at present sufficiently serious to justify alarm, though it may become more troublesome with increasing use of synthetic detergents of the present types, and it certainly calls for speedy remedy. Moreover, the presence of detergents may be adding to the existing difficulties of producing an effluent up to the required standard; and, if so, the report adds, this is cause for serious concern, and special attention is being given to this question.

The committee sum up their deliberations as follows:

“Available evidence . . . does not justify any immediate alarm in users of the public health services. There is definitely nuisance at some sewage works, however, and there are other and more serious possibilities in relation to the efficiency of sewage treatment, the condition of rivers, and the purity of water-supplies. All these matters require and will receive most careful examination.”

Medicine and the Law

NEGLIGENCE CLAIMS AT HOSPITAL

WHEN the negligence of a doctor leads to a successful claim for damages against a hospital authority, that authority has been enjoined by the Ministry of Health¹ to take legal action to make the doctor pay part of the damages. Where doctor and hospital authority are both accused of negligence, the authority, in exonerating itself, has sometimes thrown blame on its own staff; and this has been found to “prejudice that successful conduct of the defence which is in the interest of doctor and hospital authority alike.” Accordingly the Minister, after consultation with the British Medical Association and the medical defence societies, has modified present procedure.² In future, where the doctor is a member of a defence society and that body accepts responsibility for him, any payment made to the plaintiff is to be apportioned between the doctor and the hospital authority as agreed privately between them or, in default of agreement, in equal shares.

Where both the hospital authority and one or more hospital doctors are cited as defendants, the following arrangements will apply:

- (1) Any defendant may, on notifying the other(s), decide to settle the case out of court at any stage in the proceedings, but if he does so, he must accept sole liability for payment of the whole sum for which the case is settled; but each defendant shall pay his own costs.
- (2) If the defendants decide to explore the possibility of settlement out of court (and a settlement is ultimately effected), the payment made to the plaintiff shall be borne between the defendants agreed to be liable in such proportion as they may agree between themselves or, in default of agreement on the proportions, in equal shares.
- (3) If the defendants agree to defend the action in court the procedure should be as follows:
 - (a) the defendants should try to agree before the action comes to court on the proportion in which any damages and costs which may be awarded to the plaintiff shall be borne between them;
 - (b) if this proves impossible, the defendants should try to reach such agreement after the trial of the action;
 - (c) failing agreement under (a) or (b) the damages and costs awarded to the plaintiff shall be borne in equal shares between such defendants as are held liable.
- (4) In exceptional circumstances where some important legal or professional principle is involved, any defendant may

give notice to the other before delivery of defence by either party that paragraphs 1-3 above shall not apply; and the normal legal processes will then be open to all defendants.

Where either the hospital authority alone or a hospital doctor alone is cited as defendant in the action, the defendant will have complete discretion whether to fight the action or to attempt to settle it out of court. The hospital or the doctor solely cited shall not take legal action to obtain a contribution from the other, nor cite the other unless requested so to do, when the request shall be conceded forthwith. The defence societies recognise, however, that there will be cases where, although one of their members has not been cited, they might properly be asked to make a contribution towards any payment made by the hospital authority to the plaintiff, because the action or inaction of the practitioner in question was a material factor in the negligence complained of. Conversely, in actions in which a hospital doctor alone is cited, there may be circumstances in which the defence society asks the hospital authority to make a similar contribution. In either case the procedure should follow the principles set out in paragraphs (2) and (3) above, as if the party not cited were a defendant.

The success of the new arrangements (the Ministry says) clearly depends on mutual confidence between the defendants and a fully co-operative attitude on the part of both parties from the beginning, and hospital authorities are urged to bear this in mind. There should be full consultation at the request of either party in the formulation of the defence. In any case where there is a possibility of a contribution being requested from a hospital authority or a doctor who has not been cited, full information about the incident and the possibility of such a request should be exchanged at the earliest opportunity.

What is a Hospital?

Last December Mr. Justice Vaisey had to decide the fate of the Royal Midland Counties Home for Incurables at Leamington.¹ If it was a “hospital” within the meaning of the National Health Service Act, it would rest in the Minister; if it was not, it would preserve its independence. The object of the home, it may be remembered, was to give relief to persons of good character and of limited or reduced income, suffering from incurable or chronic diseases or incapacity due to injury or wounds. The rules refused admission to patients suffering from insanity, imbecility, epilepsy, cancer, or pulmonary tuberculosis, past or present. Following the findings of an arbitrator, the learned judge came to the conclusion that the Leamington home was not a “hospital” within the Act. On Thursday last, however, his decision was reversed by a majority in the Court of Appeal.²

What, for the purposes of the Act, is a “hospital”? Section 79 says it is “any institution for the reception and treatment of persons suffering from illness . . .” and “illness” is defined as including “any injury or disability requiring medical or dental treatment or nursing.” Mr. Justice Vaisey adopted the arbitrator’s finding that the only treatment at the Leamington home was palliative treatment and treatment for casual ailments; there were nurses but their nursing was not part of medical treatment.

The Master of the Rolls has now held that the arbitrator and Mr. Justice Vaisey took too narrow a view. “Treatment,” he says, in relation to a “hospital” means not only medical treatment but also nursing in the sense that patients are looked after by persons professionally trained to look after the sick. Reading the definitions of “hospital” and “illness” in section 79 together, the court could bring the Leamington home

1. Circular R.H.B.(49)128.
2. Circular H.M.(54)32.

1. *Lancet*, Jan. 2, 1954, p. 54.
2. *Times*, March 26, 1954.

within the Act as an "institution for the reception and treatment of persons suffering from . . . any . . . disability requiring . . . nursing." Lord Justice Romer agreed with the Master of the Rolls. A minority judgment, however, came from Lord Justice Denning, not for the first time. He dissented on the ground that a realistic view should be taken of what went on at Leamington. Most of the patients got about in wheel-chairs or on sticks; they were folk who would be looked after in their own homes by relatives, if the relatives could manage it; they stayed on at Leamington for years, and quite half of them went away for holidays. The staff did all they could to make life bearable for these incurables; they administered sleeping-tablets or aperients when necessary, but the amount of drugs and dressings was far less than would be used in an ordinary hospital. The Act, said the Lord Justice, drew a sharp distinction between "treatment" and "care"; care was the homely art of making people comfortable; the arbitrator had found that "such treatment as was given was merely subsidiary to the real purpose of the home," and his finding ought not to be lightly disturbed. Lord Justice Denning ended by expressing the opinion that, as the case was on the borderline, the court should decide in favour of the independence of the institution. "The voluntary, charitable institutions have served the country so well

that Parliament could only have meant to take them over when the overriding public interest demanded it."

Leave to appeal has been granted. At present two judges have voted for State vesting and two for independence. The House of Lords must tell us which two are right.

The Case of the Plaster Cast

On March 20 we summarised the proceedings at Nottingham when a child of 6 was awarded £5000 damages because her leg had suffered injury while enclosed during January in a plaster cast. A correspondent who was present in court takes issue with us on our statement that "the parents were not told of the serious condition of the child until the following June." According to a newspaper report the judge remarked that "not until six months after the plaster had been taken off were the parents told fully of the child's condition"; but in using the word "fully" the judge may well have been thinking of a complete explanation of the extent of the injury and the probable outcome. Our correspondent points out that soon after the orthopaedic surgeon saw the girl on Feb. 24 she was transferred to another hospital for further treatment and the parents at this time were well aware that the condition of the leg was unsatisfactory, though the final disability could not then be forecast.

Parliament

QUESTION TIME

Regional Hospital Boards—Administration

Mr. STAN AWBERRY asked the Minister of Health if he was aware that the areas covered by the regional hospital boards were unwieldy and too wide for maintaining the necessary close touch with the people and patients, and that it would be preferable to establish smaller all-purpose areas in which the local knowledge of committee members of conditions and circumstances could play a more important part; and if he would consider this problem with a view to altering the administration.—Mr. IAIN MACLEOD replied: The close contact that needs to be maintained with local opinion and with patients is provided by hospital management committees, and I am not aware that the areas of regional hospital boards are too large for the purposes they are designed to serve. But this is a matter which will no doubt be considered by the committee now sitting under Mr. Guillebaud's chairmanship.

Deaths from Coal-gas Poisoning

Replying to a question Mr. MACLEOD said that provisional figures of deaths from coal-gas poisoning registered in the 12 months ended Sept. 30, 1953, were 569 by misadventure and 2061 by suicide.

Sale of Worthless Products

Mr. W. D. CHAPMAN asked the President of the Board of Trade whether he was aware that worthless products claimed, respectively, to be a cosmetic lotion, a slimming aid, an eyelash grower, and a bust-improver, had been exposed for sale in Birmingham shops, and that their true contents had been described in a report of the Birmingham city analyst; and whether he would institute proceedings against the manufacturers under the Merchandise Marks Act of 1953.—Mr. PETER THORNEYCROFT replied: If I can obtain satisfactory evidence of the offer of these goods for sale, I shall certainly consider instituting proceedings.

Dental Service in Scotland

Mr. GEORGE THOMSON asked the Secretary of State for Scotland what steps he was taking to arrest the decline in the number of dental students entering Scottish dental schools.—Commander T. G. D. GALBRAITH replied: I am afraid that the position cannot be influenced directly by any action open to the Government. The Dentists Bill, which will be reintroduced as soon as Parliamentary time permits, embodies a plan for expanding dental services for the priority classes. By giving the dental profession full self-government and thus raising its status, I hope the Bill will also stimulate recruitment to the profession. Mr. THOMSON:

Is the Minister aware that entries to the Scottish dental schools have dropped from 155 in 1946 to an estimated figure of 70 last year?

Replying to further questions, Commander GALBRAITH said that in December, 1953, there were 161 dental officers in the school dental service, the highest number ever reached. In October, 1951, the number was 100, and in June, 1948, it was 131.

The number of dental courses given under the National Health Service in Scotland to expectant and nursing mothers and those under 21 years of age since the charge for dental treatment, from which these priority classes were exempt, was introduced in June, 1952, to January, 1954, was 855,300. The number of courses for the period June, 1950, to January, 1952, was estimated at 340,000.

Medical School Scholarships

Replying to Mr. SOMERVILLE HASTINGS, Miss FLORENCE HORSBRUGH, Minister of Education, said that 380 State scholarships were taken up in 1952-53 for courses leading to a medical degree at universities in England and Wales.

Family Allowances

Replying to a question Mr. OSBERT PEAKE said that, taking as children those within the age-limits laid down by the Family Allowances Act, it was estimated that the number of married couples with only one child was about 3 million, the number with more than one child who received no family allowance for the eldest child was 3,200,000, and the total number of children including those who received family allowance was 11 million.

Mr. JOHN MCKAY: Is the Minister aware that the 3 million who have only one child are half the married couples in the country who have children; that within the first and second categories in the range of income there are 1¼ million families with one child who are below the income-tax level and therefore in a bad economic position? Is he further aware that there are 1¼ million families getting 8s., 16s., and 24s. per week who are far beyond the income-tax level? Can nothing be done to achieve a fairer share of family allowances? Mr. PEAKE: All that seems well worthy of study and consideration.

Milk and Glandular Infection

Mr. D. T. LEWELLYN asked the Minister of Health how many cases in Glamorgan had been drawn to his department's attention of children contracting tuberculous infection of the glands after drinking T.T. milk.—Mr. MACLEOD replied: Six children who had consumed milk from a tuberculin-tested herd came under the notice of the local health authority towards the end of last year. The one cow in the herd found to be infected was slaughtered.

In England Now

A Running Commentary by Peripatetic Correspondents

My favourite film critic, Miss Lejeune, has been hinting for a long time that British studios can, when they really set their cameras to it, turn out comedies that make Groucho Marx wipe off his moustache and take to peddling peanuts (if he doesn't happen to be occupied that way already). Indeed, it is said that Mr. Marx once raised an eyebrow during a performance by Alastair Sim, though the significance of the gesture is in doubt, for his friends whose sanity remains are confident that he was trying to attract the attention of a young lady selling 'Coca-Cola.' For my part, I have missed many of the films on which Miss Lejeune bases her opinion, so, in the absence of a less equivocal sign from Mr. Marx, I was glad to accept an invitation to find out how things really stood by seeing last week's premiere of *Doctor in the House*. And they stand pretty well.

Dr. Richard Gordon's novel of student life at St. Swithin's Hospital quickly established itself as one of the best jokes of the day; and it has been translated so nimbly to the screen that for once Technicolor is as glorious as print. Some of the fun at the expense of doctors and students was no doubt judged too vivid for cinemagoers who are sometimes hospitalgoers as well. So, for one thing, Sir Lancelot Spratt, surgeon to St. Swithin's, is a more genial character on the screen than in the book; and though we may readily understand why he is described in after-dinner speeches as "a surgeon of the grand old school," there is only a hint of "the less charming but equivalent epithet" which his colleagues use in private. I waited in vain for one or two memorable episodes: the Christmas dance in the Nurses' Home, for example; and there was no sight of the depressing examination candidates who "write steadily and sternly, as though they were preparing leaders for next week's *Lancet*."

But the film embellishes some of the book's other events, adds new ones of its own (a devastating interpretation of bleeding-time, for example), and urges the whole business forward at the cracking pace vital to success in this sort of enterprise. Mr. Kenneth More, as the perennial Grimsdyke, is the best of a likely bunch of students, and he is, I should judge, one of the actors on whom Miss Lejeune pins her best hopes. But they all did splendidly; and I must say there was a peanut vendor with a gangling gait in Leicester Square as I went home.

A chap came into outpatients the other day who had recently survived an operation at my hands. There are two hospitals in this group, and it happened that, when he came in, he had the choice of either. Quite by chance I asked him why he had chosen St. Crispin's for his operation. "Because in St. Swithin's the mortuary is rather damp" was his reply. And he spoke with first-hand knowledge. He is the local undertaker.

He had been sent for child guidance. He did not know who his parents had been. His daddy, he said, had been a man. He had lived in Singapore all his life, they had servants, there was a baby. Now he was tall for his age, dressed in a full cowboy outfit, with loud check trousers, American-style shirt, and a ten-gallon hat. He spoke in a grown-up manner, rather slowly and with the singsong of the Babu. He was disobedient, cheeky, and continually ran away into the streets, where he wandered aimlessly. He had not settled well at school. Now he stood in the tiny consulting-room, and answered questions while his adoptive father saw the Chief.

"The Japanese came, there were bombs, our servants ran away, and we ran too; we ran to the fields, hiding in the ditches, and then we got to the jungle. My daddy was killed first though, and my mummy, too, got a splinter. Soon she died, and then I cared for the baby, but it died, and I was alone, hiding in the jungle. My friends told me where to hide."

"How did you eat, you and your baby?"

"My friends fed me and gave me food for my baby."

"Who were your friends?"

"Children like me from the village; they were kind, they knew where to hide from the Japanese, they didn't have much to eat."

"Where did they get the food to feed you?"

"They asked their parents, and each family in turn gave me something to eat, and each family in turn gave me a place to sleep when it was needed."

"How have you come to England?"

"Uncle Jim was an English soldier. When he came to my village at the end of the war, he said to me, 'Will you come and be my boy now?' and I said 'Yes.' So we went to his camp, and they all gave me sweets and cigarettes, but now I cannot smoke, or use the words they taught me. We came here on a big ship, but I was homesick for the jungle, and here I have no friends."

The wisdom accumulated against the D.P.M. failed the four registrars. No textbook catered for this sort of difficulty. None of us had an answer ready for this child who, when he returned to his own race, found that there were no friends among them like those who had kept him alive in the jungle.

* * *

Like many other connoisseurs of Edinburgh sermons, I have been dipping into the third volume of Norman Maclean's autobiography.¹ These essays strung on the thread of the life of a minister of the Church of Scotland show the skill of a *Scotsman* leader-writer, the eloquence of a great preacher, the wit and poetry of a Gael, and the "Scottish genius for suddenly making you want to burst into tears." The matter is as varied as the manner. As an exponent of social medicine I was relieved to find that the manse at Colinton—Maclean's first charge—though placed unsalubriously in a hollow beside the Water of Leith and under the retaining wall of a crowded graveyard, was sheltered from the east wind and so provided a health-giving retreat for the young Robert Louis Stevenson and other members of the Balfour family. Indeed the Colinton doctor of those days used to send ailing children to Mrs. Balfour at the Manse saying "She kens mair aboot weans than I dae"—he was a bachelor and she the mother of thirteen children. As a doctor I was encouraged by the story of the long negotiations which led to the union of the Church of Scotland with the United Free Church to hope that the medical profession will likewise, with wise statesmanship (and under pressure of public opinion and economics), emerge from its departmental rivalries and statutory divisions to a new unity.

* * *

"Oh, to be in England now that April's there!" is a heart cry of sinister import nowadays for the exiled fellows of St. Michael and St. George. The cold wars of crypto-enemies, the hot wars of the lawless, and the sell-outs to our allies have made the outposts of empire less congenial, but the home-made scientific genius of the mother country is even more disturbing to her errant lotus-eaters. It is so frightfully tiresome to have to carry a geiger-counter to the fishmonger's every week, and so awfully dreary to beachcomb in the shadow of mushroom clouds, as yet another atoll is removed around Bikini or Montebello. The Pacific now belies its name even more than when stout Cortez and all his men justifiably looked at each other in wild surmise.

And if the Pacific is a mocking name, is consolation to be found in the still-vexed Bermoothes? The Spanish Main may slumber in the noonday heat, dreaming of tourist dollars, hurricanes, and government grants-in-aid. But the shadow of Voodoo is falling again on the Antilles. Caliban rubs his hands in the undergrowth. The ghost of Blind Pew cackles hoarsely at the sight of The Black Spot. On the horizon a fore-top heralds the arrival of H.M.S. *Ben Lomond*. No export whisky for the emigrant Scot is stowed in her hold; just petri dishes, test-tubes, and guineapigs—the paraphernalia of experimental bacterial warfare.

Letters to the Editor

MEDICAL WITNESSES

SIR,—In view of the modern tendency towards litigation in relation to medical practice, it may perhaps not be out of place to remind medical witnesses that the principles of medical ethics are not in abeyance in Courts of Law.

Lawyers are apt to tell medical witnesses that it is improper, if not illegal, for them to discuss cases with witnesses called for the other side. Medical ethics demand, however, that any doctor asked to consider a matter which to his knowledge has been the subject of a report by a colleague should notify him of this fact and should also tell him what his personal view is. Neglect to follow this course may often mislead a judge and jury, since two expert witnesses may in all sincerity differ fundamentally merely because they are, in fact, talking about two separate matters. Two pathologists, for example, may examine a section from the same patient, but from a different part of him. Two sections from the same piece of tissue may show entirely different pictures.

It is important to recognise that medical and legal practices are at variance on this important point.

Westminster School of Medicine,
London, S.W.1.

R. J. V. PULVERTAFT.

TUBERCULOSIS YARDSTICKS

SIR,—The mortality-rate has long been accepted as the most reliable measure of tuberculosis in a community, and in civilised countries it undoubtedly provides relatively accurate and comparable data. The notification-rate of new cases has also provided useful information about the incidence of new cases in this country. However, while the tuberculosis-mortality rate in England and Wales has halved during the past five years, the notification-rate of new cases has remained almost unchanged. During that time the number of cases of tuberculosis on chest-clinic registers has increased by 20%, and today more hospital beds are occupied by tuberculosis cases than for many years. It may be that just as many cases of tuberculosis are being diagnosed nowadays as 20 years ago—though, of course, earlier diagnoses are being made, and many more cases of less hazardous disease are being discovered; and patients are living longer.

It seems that the time-honoured yardsticks of mortality and notification are becoming less indicative of the amount of tuberculosis in this country. What available data, if any, would be useful in estimating more accurately the significance of the "tuberculosis problem," if, as one hopes, the mortality-rate continues to fall?

In the current issue of the *N.A.P.T. Bulletin*, Pickwick points out that it is the active cases on clinic registers which really matter. These sputum-positive cases make up the "known infector pool" of infectious persons, which, together with unknown infectious cases, constitutes virtually the whole source of fresh infection in most urban areas now that milk-borne tuberculosis is being extensively eliminated. Tuberculosis will only be controlled by persistent effort, both therapeutic and preventive, to reduce the size of this "known infector pool." It is where these pools are largest and deepest that the greatest national effort toward eradication should be directed. It would be useful if health authorities could publish the number of known active cases in their area alongside their mortality and notification rates.

The offices of the Ministry of National Insurance receive initial and final certificates for every insured person who receives sickness benefit because of tuberculosis. In the local offices of that Ministry there may be valuable data that would help chest physicians in their case-finding quest. The relapse of a case believed to be

inactive could become known to the Ministry of National Insurance although the medical officer of health and the chest physician might remain unaware of the event. According to Pickwick, approximately 20% of the total tuberculosis deaths are not statutorily notified to the medical officer of health during the patient's lifetime, and one wonders whether the Ministry of National Insurance might not be able to help us to close this gap. If medical officers of health could be advised of all newly certified cases of tuberculosis, and all final certificates received, it would enable a day-to-day sickness-rate for insured persons to be kept by each local-health authority. Now that tuberculosis control is entering a new phase, it would seem that these are the sort of yardsticks that would really indicate the significance of the disease in the community.

Bournemouth Chest Clinic.

W. H. TATTERSALL.

FEWER FARMS AND MORE BEDS

SIR,—One additional 60-bedded convalescent annexe to each mental hospital would wipe out psychiatric waiting-lists. This annexe need not be staffed at all—though, of course, it would be better if it were.

In the average mental hospital each month there are 50–80 convalescent patients awaiting discharge. Most of these could look after themselves at a pinch so far as bedding, feeding, and the like are concerned. Each of the 60 convalescent beds could be turned over 5–12 times a year.

The cost? Simple. Sell the farms attached to mental hospitals—perhaps to the Ministry of Agriculture. Millions of pounds of capital are tied up—and about a million lost in the running every year.

The money, staff, and committee work spent on the farm are miserably rewarded. Very rarely is any patient discharged from the farm working-party. No Tolstolian wisdom of the soil emerges. No skill is imparted to the patients. And nothing is a more degrading spectacle than a barrow party in single-file procession, like a chain gang.

The money put into the farm, if spent on the 20 occupational therapists, educational officers, and physical-culture instructors who could be provided instead in each mental hospital, would be reflected in even better discharge-rates and in a more effective battle against institutional intellectual deterioration.

Let the end of farm psychiatry mean more staff and more accommodation.

Chester.

I. Frost.

INFESTATION WITH TRICHOCEPHALUS DISPAR

SIR,—I was much interested in Dr. MacCarthy's article (Feb. 27) on whipworm infestation in children, and especially in the possibility of using the proteolytic action of papain in treating intestinal helminths. I cannot, however, agree that her description of the clinical picture of trichuriasis is either accurate or complete.

In many tropical countries, whipworm ova are commonly found in the stools: in Southern Nigeria they were present in from 15 to 25% of specimens. The clinical picture appears to be related to the worm load, as was shown by the investigations of Jung and Beaver.¹ In brief, there may be three grades of infection: *light*, usually with no symptoms; *mild*, sometimes with allergic manifestations (urticaria) and vague abdominal pain, often in the right lower quadrant; *severe*, with prolonged diarrhoea and blood-streaked stools, abdominal pain, tenesmus (i.e., a chronic dysentery), and sometimes rectal prolapse, with whipworms easily visible to the naked eye on the mucosa of the prolapsed bowel.

As has been noted recently, however, "many authors have listed symptoms ascribed to trichuriasis, but these accounts have with few exceptions been ambiguous, inconsistent, and quite frequently far-fetched. Text-book

1. Jung, R. C., Beaver, P. C. *Pediatrics*, 1951, 8, 548.

repetitions of these lists have been vague and uncritical. . . . Chronic constipation, eructation, nervous symptoms, vertigo, etc., have been reported, but the occurrence of these with trichuriasis may well be coincidental."²

The diagnosis of trichuriasis, while usually based on stool examinations for ova, may be confirmed in some cases by sigmoidoscopy, when the helminths may be seen attached to the mucosa of the colon or rectum. The most effective treatment appears to be retention enemata of 0.2% hexylresorcinol, in water or glycerin solution, the technique of which is described elsewhere.¹

University College of the
West Indies, Jamaica.

D. B. JELLIFFE.

WATER INTOXICATION

SIR,—I should like to congratulate Dr. Wynn and Professor Rob on their very valuable paper (March 20), which should be a great help to those concerned with postoperative care and the management of fluid balance. It is clear that water intoxication must now rank with potassium loss as a new hazard to be watched for by house-surgeons and registrars, and dealt with appropriately and expeditiously.

There is one minor criticism. I have, for the good of my surgical soul and to familiarise myself with the process, developed the habit of turning mg. per 100 ml. into m.eq. per litre and back again whenever I meet them. Whereas the other m.eq. quoted in the article are correct to the nearest 10, 450 ml. of 6% NaCl are twice given, in table II and case-record 1, as containing 480 m.eq. Surely this should be 460 (actually 461)?

Although of no great importance, this small aberration makes things even more difficult for us biochemical neophytes.

Beaconsfield.

MICHAEL REILLY.

HOSPITAL, DOCTOR, AND PATIENT

SIR,—May I, as a layman, venture to comment on the recent legal actions between hospital boards and patients?

The National Health Service is young, and most people realise that growing pains are inevitable; but until the relations between specialists on the one hand and general practitioners, patients, and patients' relatives on the other have regained some of the mutual trust which existed in my childhood, these actions will continue.

Thirty years ago, my brother, then a child of six, nearly died through an error of diagnosis. Our family doctor freely admitted that a mistake had been made, and did everything in his power to put the damage right. After many months the child recovered. Although this story was freely discussed by the neighbours, I doubt if a single patient left the doctor because of it. Everybody was impressed by his honesty, his devotion to duty, his genuine understanding of the family's anxiety, and by his many simple kindnesses. It would never have occurred to my family to sue this doctor. "To err is human." Had not he saved my mother's life on several occasions, brought me through a bad attack of appendicitis, and cared for the whole family during these crises?

Recently my young son had to go into hospital for observation. It was a good hospital with modern ideas on visiting so we saw him every evening. During the twelve weeks he was in hospital, my husband and I saw the specialist twice and the house-physician once. Our anxiety was very great, and on one occasion, when we could stand the silence of the hospital no longer, my husband spoke to the ward-sister. Her reply was terse: "Oh, you intellectual parents are the worst people we have to deal with." She did not seem to realise our concern for our most cherished possession. After my son was discharged from hospital it took our doctor a fortnight and many telephone calls before he could get even a short report from the hospital on the child's condition. Four months later the clinic that we were told to attend was still waiting for a hospital report. Still, we were lucky.

2. Jung, R. C., Jelliffe, D. B. *West Afr. med. J.* 1952, 1, 11.

Tommy in the next bed had been in hospital eight months and his parents had seen the specialist once—on the night he was admitted as an emergency.

In these days when medical knowledge is put out for public consumption by radio, television, and the newspapers, as well as by the British Medical Association through *Family Doctor*, is it too much to ask that parents and relatives be given an opportunity of discussing with the doctors the patient's condition, and be given a simple explanation of what is being done for him? Certainly, I met very few parents who would not have preferred to know—even the worst—rather than face the many weeks of anxiety and uncertainty that they were forced to go through.

Would it not be possible to build up relations between hospitals, doctors, patients, and relatives into those which exist in the best parent-teacher associations of some schools, and with the same amount of good will on both sides? I cannot believe the doctors would lose anything of their status by this, and certainly some of the young housemen might benefit by supplementing their academic knowledge of disease by an understanding of the environment of their patients.

PARENT.

A COOLING UNIT IN CLOSED-CIRCUIT ANÆSTHESIA

SIR,—I have successfully used a closed respiratory circuit cooled down to 16°F to maintain heat-balance in therapeutic sweating, and I believe that a similar system in a closed-circuit unit for anaesthesia could lower body-temperature and metabolism during operations. The fall in circulation-rate with "artificial hibernation" decreases bleeding in the operation area and reduces the danger of surgical shock; but anaesthetic techniques that lower the body-temperature by drugs and/or physical cooling introduce other drug hazards difficult to control.

Before the induction of anaesthesia there is usually constriction of the skin vessels, which is often followed by a cold sweat due to mental stimuli or shock. During normal anaesthesia with a closed-circuit unit with an average volume of about 2½ litres, including corrugated tubes and mask, there is a steady rise in blood-temperature because of the continuous inhalation of warm gas of high relative and absolute humidity. The temperature of the inspired gas at the face-mask averages 102°–105°F for a Waters's absorber, and 89°–91°F for a circle unit.

These temperatures relate to a breathing rate of 18 per min., a tidal volume of 500 c.cm., and a canister of soda lime 8 cm. by 13 cm.¹ The temperature of the inspired gases in a Waters's absorber are higher than the blood-temperature, while in the closed-circuit unit they are only 8.4–7.4°F lower than blood-temperature; but both their absolute and relative humidities are high. Thus the gases in the Waters's absorber, instead of cooling the lung vascular bed, warm it. In the circle unit there is a slight tendency to cool the blood, but the cooling effect on the lung bed cannot compare with that produced by the inhalation of gas at normal atmospheric temperatures and low absolute and relative humidities.

The steady rise in temperature turns the cold sweat into a hot sweat and the skin vessels are dilated. The soda-lime container also adds its quota of heat and water to the inspired gases, for each gramme-molecule of CO₂ produces 310 calories and water. Under normal conditions only a small proportion of the heat produced is used in warming the inspired air.

These considerations suggest that we might regulate the temperature of the inspired gases by means of a cooling system before attempting to lower the body-temperature by drugs and physical cooling. A cooling system in the return circuit to the face-mask could bring down the temperature of the inspired gases to 32°F.

1. Adrian, J. *Chemistry of Anesthesia*. Springfield, 1946.

which would make induction of anæsthesia more pleasant ; and it would stop hot sweating, reduce the pulse-rate, and lessen bleeding.

Tunbridge Wells.

ANTIBIOTIC ENTEROCOLITIS

SIR,—Your excellent editorial of Dec. 12 encourages me to add some observations about the side-effects of broad-spectrum antibiotics.

Using aureomycin and oxytetracycline (terramycin) for different diseases, and especially for urogenital tract infections and amœbiasis, I was surprised to find that patients of Greek or Balkan origin did not suffer side-effects ; they were much less liable to the gastro-intestinal symptoms—nausea, diarrhœa, burning in the anorectal region, &c.—to which Anglo-Saxon patients were prone. I found that the main cause of this was the difference in their eating habits, and especially the use of yogurt, which most of the Balkan patients eat daily, especially when they are on a diet. I then started prescribing the antibiotics with yogurt, and the results were excellent.

Yogurt is a true culture of *Lactobacillus bulgaricus* plus the lactic acid produced by the fermentation of lactose. By adding 3 or 4 cups daily to the diet, it may be possible to avoid the multiplication of other resistant organisms. Whatever the explanation, I recommend yogurt as a means of preventing these side-effects. The same results can be achieved for patients who dislike yogurt by the use of preparations of lactic acid bacilli.

LEONIDAS G. POLYMENAKOS.

TREATMENT OF VARICOSE ULCERS

SIR,—A multitude of treatments have been advised for varicose ulcers, and a maze of medicaments and bandages have been applied. Firm support by bandaging remains the basis of all treatments¹ ; but not all ulcers will heal by this means alone, and something more must be done to break down the vicious circle in the lower limb.^{2,3}

In most cases varicose veins cannot by themselves account for ulceration. Varicosities generally occur in the superficial veins, and the ulcers associated with them are often small and usually heal promptly after

(a) Normal circulation ; (b) deep thrombosis in vein with associated arterial spasm and accumulation of metabolites ; (c) incompetence of valves in deep vein with accumulation of metabolites ; (d) incompetence of deep vein with communicating superficial vein.

the veins have been treated by injection or ligation. More often, ulcerated legs are the aftermath of a deep thrombosis. Instead of calling them varicose, or gravitational, it would be better to call them post-thrombotic ulcers.

The accompanying figures illustrate the changes that lead to ulceration.

Fig. a represents the normal state of the circulation in the lower limb: the arterial inflow equals the venous outflow and the circulation is in a state of equilibrium.

In fig. b a deep venous thrombosis has upset the equilibrium between inflow and outflow, which is further affected by the arterial spasm that always accompanies a deep thrombosis. Because of the deep thrombosis, metabolites accumulate, causing poor nutrition of the tissues and eventually ulceration. A slight injury may start the ulceration, or eczema may be the beginning of the trouble.

The same situation develops when the deep veins are incompetent, as in fig. c. Here the incompetence has followed a deep thrombosis, but although the thrombosed vein has been recanalised the valves remain incompetent. Hence the venous return is hampered, waste products accumulate, and ulceration follows, as in deep thrombosis.

Sometimes the deep incompetence shows itself as distension and incompetence of the superficial veins, by means of communicating venous channels, as in fig. d. It is then very easy to assume that the ulceration is due to incompetence of the superficial veins. If these veins are then injected or ligated the deep venous incompetence is not affected at all and the underlying condition is unchanged. Even the ligation of this communicating vein (in the "ankle blow-out syndrome"⁴) does not have any effect on the ulceration.

A condition indicating deep venous trouble is induration of the lower half of the leg, with the firm skin tethered down to the underlying structures. This type of leg, which I have described as the "inverted Guinness-bottle leg," is pathognomonic of deep thrombophlebitis or incompetence of the deep veins. It results from the slow inflammatory reaction set up in the tissues by the accumulation of metabolites, and it impedes the return flow still further.

The basis of all forms of treatment is compression by bandages, whether 'Elastoplast,' 'Diachylon,' 'Ceraban,' or any other of the many now on the market. The type of bandage which will prove most satisfactory depends on the tolerance of the patient's skin ; for bandages can, by themselves, set up a trail of symptoms which further tries the patient and the doctor. The aim of repeated firm compression is to get rid of the accumulated exudates and so permit healing. But not all metabolites can be dispersed in this way: it depends on how much they are fixed locally. Occasionally, the only way to promote healing is to put the patient to bed and so counteract the effects of gravity.

My purpose in this letter is to describe two other forms of treatment which I believe will also promote healing.

First, the arterial blood-supply of the leg can be increased by means of vasodilators such as tolazoline ('Prisol') or papaverine, injected into the femoral artery in the groin. Tolazoline (50 mg.) may be given once a week through a fine needle. The injection is carried out as an outpatient operation, and there is no need for the patient to rest in bed. The limb immediately becomes flushed from above downwards and its temperature rises a few degrees.

I have always thought that, in the treatment of varicose ulcers, it was wrong to ignore the arterial side of the circulation,⁵ and this method attacks the condition from the arterial side. A lumbar sympathectomy will do the same as the intra-arterial injections of tolazoline, and it will be more permanent in its effect. But patients are seldom keen on this operation, for it means a long time in bed, and they regard it as too drastic. Moreover, in these patients, who are often fat and flabby, sympathectomy is not without its risks.

Secondly, the venous return can be encouraged by using hyaluronidase ionisation to disperse the accumula-

3. Lee, M. *Practitioner*, 1953, 170, 288.

4. Cockett, F. B., Elgan Jones, D. E. *Lancet*, 1953, 1, 17.
5. Anning, S. T. *Brit. med. J.* 1949, 11, 458.

tion of metabolites. For this treatment, the patient must attend a physiotherapy department regularly. There is no doubt that it has an effect: in very many cases the tissues become softer, and in some the pain is relieved. This form of treatment is most useful in the post-thrombotic leg before ulceration takes place—a condition in which pain is often intense when the patient is up and about. I have noticed that the pain becomes less as soon as ulceration occurs, probably because there is then an outlet for the accumulated metabolites.

Thus, by a combination of compression bandages, tolazoline injections for the arterial side, and hyaluronidase ionisation for the venous side, one hopes to interrupt the vicious circle and restore the circulation to normal, or as near normal as possible. Probably the Bisgaard treatment, for which such success is claimed, has the same effect as hyaluronidase treatment in dispersing the metabolites.

The various operations described for excision of the ulcer and for skin-grafting seem to me to be based on false premises, and the successes attained with them are perhaps due to the patient having to remain in bed. Again, a skin-graft applied to such an unhealthy site as an ulcerated leg is likely to break down when the patient gets about again, and this in fact happens time after time. Such operations as ligation of the communicating veins do not attack the underlying condition.

MAURICE LEE.

CONTROL OF CANCER MORTALITY

SIR,—With reference to Professor Smithers's letter of Feb. 13, it seems necessary to point out again that the appraisal (through vital statistics) of the value of treatment, early or otherwise, in preventing death from breast cancer was based on those rates which showed good evidence of reliability. Firstly, there was the consistent maintenance of level trends in the recorded age-specific breast-cancer mortality (except that in old age), in spite of vastly different circumstances from which the rates were derived—differences in time, in place, in provision and availability of diagnostic and treatment services, in utilisation of specialist services and hospital accommodation, in acceptance of extensive investigation and treatment, in economic situation, in "cancer education" of the public and of the profession, in the speeding-up of treatment, in publicity and propaganda, and with the book-keeping done under the same and under different auspices. The only reasonable explanation of that stability and uniformity in the trends is that the recorded rates are highly indicative of reality and practically insusceptible to the influence of artificial factors.

Further, any contention that the rates deriving from such different and changing conditions were maintained at their respective levels by similar changes in diagnosis (at death) or in certification asks too much of credulity. Secondly, if any material proportion—say, even 10%—of the mortality charged to breast cancer were actually due to other causes, the declines in mortality from causes other than cancer in women under 60 years of age in the past 25 or 30 years should have yielded an appreciable concomitant decline in the recorded breast-cancer mortality of those age-groups. The lack of decline is substantial evidence that the mortality charged to breast cancer in those age-groups did not contain any appreciable proportion that was not caused by breast cancer. Thirdly, when the selection of cause of death was made the responsibility of the physician—in 1939 in England, in 1949 in the U.S.A., and in 1950 in Canada—changes in the rates resulting from that change in selection were almost entirely confined to the rates in the older age-groups. The paucity of the change, if any, in the rates in other age-groups—on which the comparisons were based—is further consistent evidence of the reasonable reliability of those rates. Thus, the trends do not show

any of the characteristics that they should show if Professor Smithers's contention that the mortality charged to breast cancer included any material proportion not caused by breast cancer were valid. On the other hand, they show very substantial internal evidence of their reliability.

Professor Smithers contends that the very early spread as shown by the various analyses provides a sound reason for still earlier treatment. This contention would be timely if there were some means of detecting breast cancer before the appearance of a tumour or discharge or any other sign or symptom. The attack on the very early and on so-called "pre-cancerous" conditions, as in Saskatchewan, Ontario, and Massachusetts, has failed to effect any assured reduction in mortality. Thus, without means of earlier detection of cancer the contention is hardly pertinent.

I am sorry that my writings have given Professor Smithers "an uncomfortable feeling" that I will misconstrue or otherwise evade any evidence of progress that may come in the future. I do not know the basis for his "horrible imaginings," but let me assure him that I will neither misconstrue nor evade any sound evidence. As he well knows, however, neither feelings nor opinions nor impressions nor beliefs nor even the most favourable interpretations of ambiguous data constitute sound evidence.

I have never inferred, much less implied, that all the efforts towards earlier diagnosis and better treatment have been "entirely a waste of time." One has only to recall John Brown's *Rab and His Friends* to be acutely conscious of the progress that has been made in the past century. And the fact that breast-cancer mortality showed no change coincident with the introduction and use of effectual chemotherapy for infection indicates clearly that the earlier risks of infection in treatment had been well met by the surgeons before the advent of the sulphonamides and antibiotics. Although I am concerned only with evidence and not with what anyone, myself included, says or opines, perhaps it is fair to say that I have stated repeatedly and I fully concur that treatment of all cancer and all pathological conditions is fully justified, even when it gives only mental or physical relief as in the case of cancers that kill by remote metastases (e.g., most breast cancers), or definitely postpones death as in the case of cancers that kill by local extension before metastases cause trouble (e.g., many bowel and pelvic cancers), or gives complete cure as in the case of non-metastasising cancers (e.g., the vast majority of skin cancers or what are called skin cancers). One would surely be queer who did not admit and admire the improvements in and the results of treatment of laryngeal cancers as well as others, including breast cancer, but, gratifying as they are, they should not lead us to claims beyond our capacity or blind us to our present limitations. Even in lethal breast cancer there may be, as Sir James Paget pointed out a century ago,¹ an occasional case in which "by happy chance" the lesion can be removed before remote spread occurs. But the number of such cases, if any, must be too small in relation to the whole of breast cancer to make any decisive impression on the mortality-rates; no more precise measurement of that number is available today. And no-one, surely, doubts that a healed lesion is infinitely preferable to an ulcerated, infected, sloughing mass. I hope this clears up any misconceptions which either Professor Smithers's or my words may have left.

Reference can now be made to the further consistent evidence of the early remote lethal spread from the primary cancer, provided by Williams, Murley, and Curwen.² Different methods of treatment—radical

mastectomy, simple mastectomy, irradiation, &c.—were equally effective, as measured by survival-rates, in spite of the fact that regional recurrences were less frequent in cases treated by radical mastectomy. The authors point out “that all methods of treatment may have been equally ineffective in prolonging life.”

SENSITIVITY TO ISOPRENALINE

SIR,—I think it is worth while placing on record the case of a man of 54, with chronic asthma, who has become sensitive to isoprenaline. I started him on isoprenaline for his asthma in September, 1953, which gave him considerable relief. On Nov. 18, however, he sought advice because of a persistent sore mouth with redness and vesiculation, particularly in the soft palate but involving also the whole buccal mucosa. It was established by repeated trial that this was undoubtedly due to tablets of isoprenaline sulphate, and he has been free from this trouble since stopping the tablets.

Workington.

R. N. R. GRANT.

TRAINING OF NURSES

SIR,—I agree with Dr. Findlay (Feb. 6) that there is need for radical changes in the nursing syllabus if we are to maintain an efficient and effective service in the future.

Three main types of nursing staff are needed :

(a) Highly intelligent, academic, and technically minded girls who will form the teams for specialist units—e.g., thoracic, neurological, and general operating in all types of hospitals.

(b) Equally gifted but more socially minded women for ward sisters, suited to become the educators of families and patients, and able to cooperate with lay social workers. These nurses should become the key workers in every hospital and public-health department.

(c) Semi-skilled attendants forming perhaps 60% of the service. It used to be the practice—a wholly sound and sensible one, I think—to give these people only the simplest theoretical training. Many of them are still giving devoted service, but they are a dwindling band; the truth is we are not replacing them, and, with an ageing population and the introduction of shorter duty hours, recruits are urgently needed.

Can it be expected that any one syllabus would do for these three groups, any more than one would expect an industrial concern to train scientists, engineers, and factory hands as one group?

At present there are two main curricula: the basic general training with S.R.N. qualification; and the assistant nurse course with S.E.A.N. status. The final result is that the academically minded girls who stay the course get into the specialist teams, but far too many of them are lost, because valuable specialised training is being given to too many people, most of whom are frankly bored with it, while the keen ones get side-tracked into taking more certificates, just to keep their wits sharpened. The second group are being offered many new incentives as industrial nurses and social workers, but most of them remain to form the solid core of the nursing service. The third group should, I think, have the opportunity to go straight on to the wards for the first six months of their training and then receive very simple instruction with a strictly practical bias, lectures and written work being reduced to a minimum.

When I advertise for staff I always get replies from *trainee* assistant nurses; and I always make a point of seeing them to find out why they will risk leaving the security of a hospital. Invariably, they say they are tired of the theoretical side of the work; and many are the wrong type, but have been taken on because they have a pair of hands. In one hospital near my home, the assistant nurse trainees draw just a little over £7 monthly after all deductions; this hospital has a costly training scheme, a permanent advertisement in the nursing press,

and a chronic shortage of staff. Maybe this is an exception, but I doubt it.

This whole question of nursing recruitment, selection, and training, is urgent. It would be a help if some simple psychological test could be applied to weed out the immature and the frankly hysterical, who because of their lack of staying power are costly, and who, if they do stay the course, do so at tremendous cost to themselves and their patients. As for an overhaul of the whole syllabus, it would be interesting to know if Dr. Findlay has any definite scheme in mind. Would he have a basic training for all nurses, or two schemes with many modifications, as at present?

MATRON.

POLIOMYELITIS IN CHILDREN'S WARDS

SIR,—Dr. Ferguson (March 27) draws timely attention to the “increasing awareness of the connection between paralytic poliomyelitis and injections of all kinds.” The interest and concern occasioned by evidence of association between immunising injections and paralytic poliomyelitis have perhaps lessened the attention which would otherwise have been paid to paralysis occurring in conjunction with other kinds of injection.

Dr. Stanley Banks (Feb. 27) inculcates parenteral penicillin, and there is reason to believe that other injections may be fraught with comparable hazard. In 1952, an adult woman had facial palsy due to poliomyelitis; a very short time before she became ill, she had had dental treatment involving injections on the same side. In 1953 Dr. J. K. Grant, medical officer of health for Great Yarmouth, informed me of a resident from this area, in whom poliomyelitis presented with a unilateral palatal palsy, shortly after dental treatment involving a maxillary injection on the same side.

One is compelled to the conclusion that when poliomyelitis is prevalent in an area, it may be wise, particularly in dealing with children, to reserve injections for those conditions which are urgent, if there is no acceptable alternative to the intramuscular route for administering the therapeutic agent of choice.

J. STEVENSON LOGAN
Medical Officer of Health.

Southend-on-Sea.

PATHOLOGISTS AND PNEUMOCONIOSIS

SIR,—My letter of March 20 was not meant as a personal attack on Dr. Triger, but as a protest against all those who, without proof, assume greater accuracy and validity for one method of diagnosis than for another. Dr. Triger last week accuses me of the very assumption against which I was protesting. I did not claim that “clinical and radiological diagnosis of industrial dust disease is more reliable than post-mortem diagnosis,” but only that the errors and validity of the former have been studied and that until pathologists have done the same they cannot play the rôle of assessors.

It is interesting that while Professor Browne and Dr. Triger agree that the radiograph is a mere “shadow,” they disagree as to the “substance” of the problem. The one (a clinician) holds to disability, the other (a pathologist-clinician) to the post-mortem diagnosis. I certainly consider the function of the lungs in life more important than their appearance after death. We need to know much more about the effects of dust inhalation upon pulmonary function before we can really assess the incidence of “pulmonary dust disease”—a term that may have much wider implications than the present legal definition of pneumoconiosis. Meanwhile, we know that, in many cases, the “shadow” in the radiograph today may portend the “substance” of disability tomorrow, so it should not be ignored.

Among many sources of sampling error in post-mortem statistics, the most important is the very one that Dr. Triger mentions in seeking to deny them! Post-mortem

examinations are, as he says, selectively carried out on cases where pneumoconiosis is suspected as a cause of death. Those in which the suspicion does not arise tend to be excluded whether they have pneumoconiosis or not.

Surrey.

C. M. FLETCHER.

ORDINARY YOUTHS

SIR,—To my religious bias revealed by Dr. Malleson (Feb. 27) and now my emotional bias discovered by Dr. Logan and Miss Goldberg, let me add a third, an intellectual bias; for clarity as against obscurity. It has been sorely tried by the letter from the last-named correspondents in your issue of March 27. Parts of it are as incomprehensible to me as were parts of the original article.¹

But Dr. Logan and Miss Goldberg made it quite clear that they accused me of irresponsibility in attributing implications and interpretations to their writing which were not true. This is a serious allegation, and one, if proved, deserving of the strongest possible censure.

But what are the facts? On Feb. 13 I commented astringently on your leader of Jan. 23, based on the article by Dr. Logan and Miss Goldberg. In my letter I gave a long quotation from their article: there was not the slightest wish or attempt to distort the meaning of the extract; enough only was given (as I thought) to exclude any suggestion that I was taking it from its context. (What more could the authors want? They already had had 1½ pages in your leader.)

In the quotation, all 74 youths under survey had indicated their approval of premarital sexual intercourse with a "steady" girl friend. At the end of my letter, I wondered what precisely were the implications of the last sentence in the quotation: that "there does seem to be evidence, however, that these young people were reaching towards a freer and less guilt-ridden expression of heterosexual relationship, and that this may become an important factor in mental health."

Since there then followed complete silence on the authors' part, I indicated in my reply to Dr. Malleson on March 6 what this sentence meant to me: "that there was evidence that uninhibited premarital sexual intercourse would be beneficial to the mental health of young people."

Meantime, however, I had done some literary research; small, but significant.

I submitted the quotation given in my letter to 12 senior members of the staff of this University, including 7 professors; a mixed bag from the faculties of art, medicine, science, and divinity. (I only, for religious bias!). Such men are more than usually alive to the dangers of quotation out of context, and more than usually precise in the use and understanding of words. With one exception (and he did not allege the quotation was unfair to the context), they all agreed with the implication I put on the sentence. In the face of such evidence, it is difficult to accept the authors' excuse for not replying to my first letter—that they believed my wrong emphasis would be obvious to everyone.

Before leaving your readers to judge where the "irresponsibility" in the use of words properly rests, I should like to advert to the corollary from this literary investigation.

We have it on the authority of Dr. Morris (Feb. 27), of the Medical Research Council, that the research on these 74 youths was no hurried collection of facts and opinions for some ad-hoc purpose; the report on it was 4½ years in gestation. If the authors, after such a period for reflection and choice of words, on a matter of such vital importance to everyone interested in the health and education of young people, could be so obscure and ambiguous that a group of highly intelligent men understood them to mean what they, the authors, now so violently repudiate as their intention, what con-

ceivably was the state of confusion in the minds of the 74 rising eighteen-year-olds, confronted with questions from the same authors, ranging from the virginity of their sisters to that of their wives-to-be; and what kind of answers and stories could be expected of them? Hans Andersen?

Most people will learn with relief that Dr. Logan and Miss Goldberg repudiate the advocacy of that sexual behaviour for the young, which so many of us believed, however mistakenly, their article to imply. But the fault lay in their obscurity, not in our understanding.

A. STEWART HENDERSON
Medical Officer to Student Health Service,
University of Glasgow.

Obituary

ERNEST HENRY MARCUS MILLIGAN

M.D. Belf., D.P.H.

Dr. E. H. M. Milligan, for many years medical officer of health for Glossop, died on March 22 at the age of 75.

He was born in Belfast, the son of Seaton Forest Milligan, M.R.I.A., and he was educated at the Methodist College and at Queen's College, Belfast. After studying law he turned to medicine and graduated as M.B. in the old Royal University in 1906. After holding a resident appointment at Purdysburn Fever Hospital in Belfast he proceeded to his M.D. degree in 1910. The following year he took the D.P.H. and became M.O.H. for Long Eaton in Derbyshire. In 1917 he was appointed school medical officer for Bath, but in 1920 he returned to Derbyshire as M.O.H. for Glossop, a post he held with distinction for twenty-five years. His chief interest was nutrition, and with officers of the Ministry of Health and of the Medical Research Council he shared in dietary, dental, and clinical surveys, in trials of the nutritive values of dried yeast, and in emergency feeding preparations. But he also found time for work of his own, including therapeutic trials with vitamin preparations. In 1946 he retired but he soon joined the staff of the Ministry of Health to conduct nutrition inquiries. For the next four years he was happy in this work, and he did not spare himself, but was always ready with fresh schemes for inquiry and research. Most of his clinical work for the Ministry was published in progress reports in the *Monthly Bulletin*; during the last year or so he made extensive surveys of hæmoglobin levels in women during and after pregnancy.

H. E. M. writes: "I first met Milligan in 1934 when he wrote to the Board of Education for advice about the nutrition of the children in his borough.

"In those days Glossop was a distressful place; some 60% of its working population were idle with no prospect of employment. In such conditions, complacency or discouragement might have been excused, but escapism of this sort was foreign to his nature. To him the situation was a challenge, and he faced it with an enthusiasm which carried him beyond his immediate goal into the field of research.

"Probably the official interest in his problems encouraged him to launch the nutritional activities which were to remain his absorbing interest. The first practical outcome was the 'health sandwich' in 1934, based on the same principles as the Oslo breakfast, which it anticipated by some two years. The presumption was that the home diets of the children were deficient in constructive and protective nutrients; dietary surveys later made this abundantly clear. It was, therefore, common sense that the school supplement should make good these defects. Later, when school meals were introduced Milligan's logical mind was uneasy because the composition of the proposed meals did not conform as closely to these principles as his own carefully designed sandwich. His protests were not in vain, and the constitution of the meals was in due course modified.

"The classification of children into the four nutritional categories recommended by the Board of Education—excellent, normal, slightly subnormal, and bad—was not good enough for Milligan; it savoured too much of the art and too little of the science of medicine; there must be some objective measurements of physiological efficiency to support such assessments, for the nutritional state is a physiological

1. *Brit. J. Sociol.* Dec. 31, 1953, p. 323.

concept. He seized eagerly on the dynamometer as a means of providing such data, and later developed his test of endurance. But his irrepressible enthusiasm would not let it rest there. He had to see how these measurements were related to a wide variety of anthropometric data, sitting height, chest expansion, and so on, and later to the hæmoglobin and phosphatase of the blood. The masses of data which he collected provided him with a new field of endeavour in mathematics and statistics; how many of his working hours were spent in exploring the many hypotheses conceived by his fertile brain, only his family can tell.

"Despite eccentricities he drew people towards him and suspicion eventually gave way to affection. His fund of ideas and schemes of research—all of a practical bent—seemed inexhaustible. His reading of medical and scientific literature was wide and profitable; the extent of his knowledge of physiology as well as of public health and clinical medicine was remarkable. Though frail in physique he was tough. He had a perfectly clear vision of his purpose which, I am convinced, was to do his utmost for the good of his fellow men, particularly those placed in his charge. He was not deterred by obstacles and pursued his purpose unselfishly to the end of his life. Only a few months before his death he wrote several articles to the Manchester papers explaining the nutritional significance of the reintroduction of white flour.

"He had many literary affiliations; his sister, Alice Milligan, who died last year, was the well-known Irish poetess. He was an active member of the Irish Literary Society and he had written short plays for the radio and some poetry. He also had a good knowledge of Gaelic literature. Had he been able to discipline his bright intelligence he would doubtless have risen high in science or medicine, perhaps even in literature—but he would have been very different. As it is, many friends in England and Ireland will mourn a courageous and determined seeker after truth who was tolerant of most things except injustice or hypocrisy."

Dr. Milligan was extremely happy in his family life, and two years ago he returned from the Midlands to Glossop to be near his grandchildren. He leaves a widow and three daughters, one of whom is a doctor.

FRANCIS BRETT YOUNG

M.B., D.Litt. Birm.

IN some of his best novels Francis Brett Young acted as an informed and sympathetic interpreter of his own profession. And whatever he wrote about he wrote as a doctor. "There is nothing in the world," he once said, "which so fits a man of letters to wrestle with the mind of man as an intimate acquaintance with his body. Literally and figuratively the doctor sees thousands of men and women naked: he sees the spring of curious motives, he shares strange secrets. A man or woman will tell lies or feign emotion to the pastor or lawyer. With the physician they know that only the truth will help them." Brett Young's training as a doctor served well his talent as a writer, and much of the strength of his work lay in his capacity for impartial, shrewd, yet sympathetic observation.

The son and grandson of a doctor, he was born in 1884 at Halesowen in Worcestershire. From Epsom College he went to the University of Birmingham, where he graduated as M.B. in 1906. Even before he qualified he had decided that he would rather be a writer than a doctor, and after a voyage to Japan as ship's surgeon he settled in a country practice in Devon which left him leisure to write lyric poetry and settings for the poems of A. E. Housman and Robert Bridges. Before this way of life was interrupted by war in 1914, he had already written three novels.

With a commission in the R.A.M.C. he served during the war as R.M.O. in the Rhodesian Regiment under Field-Marshal Smuts, and he has described these years in *Marching on Tanga*. Invalided home with malaria, he lived for the next four years at Anacapri, writing steadily. *The Young Physician*, a partly autobiographical novel, centred on the Birmingham Medical School, was published in 1918. In 1927 the *Portrait of Clare* brought him the James Tait Black prize and established his reputation. Though it is not a description of medical life, in the octogenarian Dr. Weir it contains a memorable portrait of a country doctor. *My Brother Jonathan*, perhaps the most famous of the medical novels, which appeared in

1928, was the story of the daily round of a slum practice, lacking in glamour but full of humanity.

For many years, besides his house at Anacapri, Mr. Young also had a fruit farm in Pershore, and he continued to cherish his associations with country life and with the Midlands. But after the late war he settled in South Africa, and he died in Cape Town on March 28.

HAROLD GEORGE WILLIAMS

M.R.C.S., D.P.H., D.P.M.

Dr. Harold Williams, a psychiatrist to the London County Council, died at his home in Hampstead on March 21 at the age of 51.

He studied as an engineer before qualifying in medicine from St. Thomas's Hospital in 1931, and he always took great pleasure in the skill of his hands, which he showed particularly in his drawing and painting. After a period of ill health he decided to leave general practice, and, during the war, he took the diplomas of public health and psychological medicine. He worked for a time as medical director of the child-guidance clinic in Canterbury before he joined the central staff of the L.C.C. in 1949 as a whole-time (what he called "odd job") psychiatrist.

D. P. writes: "During these last five years Dr. Williams held an unusual position, and he has been an important influence in the development of the work of his colleagues both medical and lay, and in the changes that have taken place in the care of children not only in the L.C.C. public-health department but also in the education and children's departments. He was closely concerned with the education of maladjusted children, the child-guidance service, and the beginnings of preventive mental health work, as well as with the care of his child patients. It may have taken some time for those who worked with him to appreciate the Freudian philosophy that underlay his recommendations, but all soon learned to rely on his integrity, which he maintained in what were sometimes difficult conditions."

Dr. Williams leaves a widow, Dr. Miriam Williams, and a young son.

Appointments

- LITTLE, B. R., M.R.C.S., F.F.A. R.C.S., D.A.: consultant anaesthetist, Bristol clinical area (Weston-super-Mare).
 MCCARTHY, DENIS, M.D. N.U.I., M.R.C.P.I.: resident medical superintendent, St. Kevin's Institution, Dublin.
 MOLONY, CONOR, L.R.C.S.I.: resident medical superintendent, City Home and Hospital, Limerick.
 ROWLANDS, IRENE P., F.R.F.P.S., M.R.C.P.: geriatrician (S.H.M.O.), North Gloucestershire clinical area.
 STANTON, J. B., M.B. Camb., M.R.C.P., D.P.M.: asst. neurologist, Northern General Hospital, Edinburgh.
 VAUTIER, C. K. J., M.B. N.Z., M.R.C.P., D.M.R.D., D.C.H.: consultant radiologist, Merthyr and Aberdare H.M.O.
 WALTON, H. C. M., M.B. Camb.: consultant pathologist, Swansea.
- East Anglian Regional Hospital Board:**
 LOPERT, HEATHER J., M.B.: anaesthetic registrar, Peterborough Memorial Hospital.
 SALMON, J. M., M.B. N.U.I.: asst. chest physician, Great Yarmouth and Lowestoft chest clinic area.
 WELSH, R. I. H., M.B. Witwatersrand, F.R.C.S.: surgical registrar, Peterborough Memorial Hospital.
- South Eastern Regional Hospital Board, Scotland:**
 MACGREGOR, T. N., M.D. Edin., F.R.C.S.E., F.R.C.O.G.: consultant obstetrician and gynaecologist, Western General Hospital, Edinburgh.
 MOLEOD, H. M., M.B. Edin., M.R.C.P.E.: asst. tuberculosis physician (S.H.M.O.), East Fortune Hospital, North Berwick.
 TURNBULL, F. W. A., M.B. Edin., M.R.C.P.E.: tuberculosis physician (S.H.M.O.), Royal Victoria group of hospitals, Edinburgh.
- South Western Regional Hospital Board:**
 BURROWS, W. L., M.D. Belf., M.R.C.P.I.: clinical asst. in general medicine, Royal United Hospital, Bath.
 COLLINS, J. R., M.B.: general-practitioner anaesthetist, Newquay and District Hospital.
 DORAN, H. J., M.B. Belf., D.L.O.: clinical asst. E.N.T. surgery, Exeter clinical area.
 REES, D. I., B.M. Oxid, D.L.O.: general-practitioner anaesthetist, Stroud General Hospital, Glos.
- The Hospital for Sick Children, Great Ormond Street, London:**
 KIRKMAN, DAPHNE M., M.B. Lond.: house-physician.
 MONTGOMERY, J. N., M.D. Belf., M.R.C.P., D.C.H.: resident asst. physician.
 PARKINSON, T. J., M.B. St. And., B.Sc., M.R.C.P., D.C.H.: house-physician.
 PENRY, B. J., M.R.C.S.: house-surgeon.
 SILBERSTEIN, E. P., M.B., B.Sc.: house-physician to the neurological and neurosurgical department.
 THOMSON, MARY F., M.B. Glasg.: resident M.O., Tadworth Court.

Notes and News

EHRlich CENTENARY EXHIBITION

To mark the centenary of the birth of Paul Ehrlich, "father of chemotherapy," the Wellcome Historical Medical Museum has prepared an exhibition at the Wellcome Foundation, Euston Road, London, N.W.1. It was opened on March 25 by Sir Henry Dale, O.M., F.R.S., chairman of the Wellcome Trustees. Among those at the ceremony were Miss Martha Marquardt, Ehrlich's secretary from 1902 to 1915, and Dr. E. Ashworth Underwood, director of the Wellcome Historical Medical Museum. Mr. M. W. Perrin, chairman of the Wellcome Foundation, presided.

Sir Henry announced that the Wellcome Trustees had agreed to publish a collected edition of Ehrlich's works; and it is hoped that this will appear later in the year. It will contain all his published and a large number of his unpublished papers, each being reproduced in the original language (thus, Ehrlich's Harben lectures will be in English). They have been collected by Sir Henry, Miss Marquardt, and Dr. Himmelweit. Sir Henry told how some of the exhibits had been rescued from Ehrlich's ruined institute at Frankfurt after the war, and how others were in a chest of documents which his widow had taken with her when she was driven out of Germany. Now, with the help of his grandsons, these papers had been made available to the Wellcome Museum on indefinite loan. Sir Henry suggested that the future would come to regard Ehrlich's contributions in medical treatment as ranking with those of Lister in surgery, though Ehrlich was at heart an inorganic chemist and a biochemist.

Sir Howard Florey, F.R.S., contrasted the orderly methods of Ehrlich with what he described as the hit-or-miss-waiting-for-something-to-turn-up approach which was prevalent in the search for new remedies in chemotherapy today.

The exhibition includes photographs of Ehrlich at work in his study: "in spite of the apparent chaos Ehrlich could find any paper that was required," the caption says. Beside two yellow cards or "blocks" containing instructions by Ehrlich, the comment is: "The writing and brief note form frequently gave the assistants some difficulty in interpreting the instructions." Examples of the work of those associated with him include a paper in THE LANCET in 1907 by Prof. Carl Browning, F.R.S., entitled Experimental Chemotherapy on Trypanosomes Infections: it was Ehrlich who coined the term "chemotherapy." Around the diploma of the Nobel prize awarded to Ehrlich in 1908 for his work on immunology are grouped some of the other honours that he won. Admission to the exhibition is free.

ALMONERS AT DINNER

By the end of last year the Institute of Almoners had a subscribing membership of 1579, including 1174 in active work; and the annual meeting held in London last Saturday was again impressive. Prof. A. L. Banks, F.R.C.P., of Cambridge, gave the principal address, entitled Clients and Patients.

At the annual dinner Miss Enid Warren presided and the toast of The Institute was proposed by Sir Arthur Howard, chairman of the board of governors of St. Thomas's Hospital. In these days, he said, when so many fine titles, such as *adile*, *manciple*, and *seneschal*, have disappeared, it was encouraging that that of almoner persists. A working definition of it would be "one who with sympathy and skill does good by stealth"; and Sir Arthur emphasised the necessity for both sympathy and (with strong support from Florence Nightingale) skill. The power of doctors and nurses to help their patients had been immensely increased by the work of almoners in relieving those patients' anxieties both before they came into hospital and after they left it. At St. Thomas's, where "almoners" had been appointed in 1557 to look after the day-to-day affairs of the hospital, the proposal some fifty years ago to have a lady almoner caused no small perturbation, and the post was projected as that of "lady inquiry officer." Nevertheless Miss Annie Cummins was appointed lady almoner in 1905: and, though she always wore a hat (to show that she did not regard her status as permanent), she started a great tradition, directly inherited and enhanced by Miss Morris. Responding, Miss E. C. Morris looked back over forty years but found the present more exciting. The main problem was numbers, for "matrimony winnows our ranks"; but the profession was now recruiting men. (Not that this was new: she recalled, in the

old days, a little bearded gentleman—an assiduous attender of committees—who was always known as "the lady almoner of the Metropolitan.") Miss Morris rejoiced in the two-way traffic between the United States and the United Kingdom, and in the splendid profession that has grown up in Australia. As for the effects of praise on herself and her colleagues, she recalled the remark of Mr. Adlai Stevenson when a friend said: "Will all these things go to your head? Will you be a less good person?" "No, it's quite all right," said Mr. Stevenson, "provided one doesn't inhale."

After Miss M. J. Roxburgh had dealt with The Guests informatively but gaily, Dr. Albertine Winner described almoners as professional colleagues in the highest sense of the word: "It is," she said, "your professionalism that endears you to all of us." If she were to choose one epithet for the profession it would be a *grown-up*—and she could think of no higher compliment. Moreover she was proud that the calling of almoner was almost entirely the creation of women, and she hoped that when men enter it (bringing their own intellectual contribution) they will not destroy the feminine touch—the feeling of understanding and tolerance of what is essentially a maternal profession.

SEX AND SOCIETY

THE April issue of the *Practitioner*¹ contains a symposium on Sex and its Problems. The first article, by the Bishop of Rochester, gives a clear summary of the attitude of the church to sexual life, marriage, promiscuity, divorce, contraception, artificial insemination, and homosexuality. Four articles are devoted to homosexuality. The first, by Dr. C. G. Learoyd, sorely lacks objectivity; the medical aspect is well dealt with by Dr. W. Lindsey Neustatter, endocrinology by Dr. G. I. M. Swyer, and the criminal law by Mr. John Maude, Q.C. Dr. Joan Malleson describes the sexual problems of the woman in early marriage who suffers coital discomfort, and gives advice on simple treatment. Dr. David Stafford-Clark discusses the aetiology and treatment of impotence in a paper which should enable the practitioners to help many of these patients. Other articles are devoted to prostitution, the celibate male, premarital chastity, and sex problems at adolescence, in the unmarried women, at the climacteric, and in old age. The article on sex problems in the Services is rather sketchy; the question of the immaturity of the National Serviceman is hardly touched on, though surely this is the point about which the doctor is likely to be approached by anxious parents. The concluding article, on criminal aspects of sexual abnormalities, written by the Chief Constable of Nottingham, offers little but punishment.

A PHYSIOLOGIST HONOURED

Prof. Alexander Lipschutz is known for his early discoveries in the field of endocrinology. Outstanding among these were the conditions for successful gonadal grafting; the reactions of an ovarian fragment after removal of the rest of the ovarian tissue from the body, which led him to formulate the "law of follicular constancy"; the disturbance of quantitative relations between pituitary and ovary when a fragment of the ovary remained, resulting in failure of the fragment to check hypophyseal function; and much fruitful work with his associates on the tumorigenic and opposing actions of certain steroid hormones.² Associates and friends from all over the world have contributed to honour the occasion of Professor Lipschutz's 70th birthday in *Acta Physiologica Latino-Americana*.³

In his introduction to the dedicatory issue of this journal, Prof. B. A. Houssay, for. mem. R.S., refers briefly to the life and work of Professor Lipschutz in Europe and America. Of the thirty-one papers in three languages several confirm and extend Professor Lipschutz's own observations. Prof. S. Zuckerman, F.R.S., reports experiments which conform with a main presupposition of the law of follicular constancy, in so far as they indicate that oögenesis ceases before puberty in the rat, rabbit, and monkey. He reminds us, too, that as long ago as 1929 and 1930 Professor Lipschutz found that desiccated ovarian tissue that had lost 50% of its original weight would still "take" when grafted. No "takes" were obtained from this tissue when kept at 0°C. A. S.

1. Published at 5, Bentinck Street, London W.1. 7s. 6d.

2. Lipschutz, A. Steroid Hormones and Tumours. Baltimore, 1950.

3. *Acta physiol. Latino-Amer.* 1953, 3, 49.

Parkes, F.R.S., summarises some of his own and his colleagues' experiments on the conservation of gonadal tissue for transplantation, thus drawing attention to the remarkable property of glycerol in protecting living cells against the effect of low temperature. Nakahara⁴ may have been the first to make use of this preservative property of glycerol for dried and frozen mammalian cells.

Among many other unrelated but no less interesting subjects, there is a delightful historical research by G. W. Corner into the discovery of smooth muscle, and an elegant demonstration by W. Buño of the direct action of cortisone in degranulating mast-cells.

University of London

The title of professor of cytogenetics has been conferred on Mr. P. C. Koller, D.Sc., in respect of the post held by him at the Institute of Cancer Research, Royal Cancer Hospital.

University of Manchester

At recent examinations the following were successful :

D.P.M. (part II).—D. L. Fox, Kenneth Rawnsley.

University of Sheffield

The bequests, of about £50,000, made to the university by Sir George Franklin, pro-chancellor from 1905 to 1916, and by Miss Daisy Franklin are to be used to endow a full-time chair of medicine to be known as the Sir George Franklin chair.

Royal College of Obstetricians and Gynaecologists

At a meeting of the council held on March 27, with Mr. A. A. Gemmell, the president, in the chair, Edward Solomons was admitted to the fellowship.

Association of Surgeons of Great Britain and Ireland

This association is holding its annual meeting in Leeds from May 13 to 15. Prof. Alfred Blalock (Johns Hopkins Hospital, Baltimore) will deliver the Moynihan lecture on the Expanding Scope of Cardiovascular Surgery. The programme also includes discussions on Hiatus Hernia; Ulcerative Colitis; Exophthalmos; and Duodenal Diverticula.

Nutrition Society

On Saturday, May 8, at 11 A.M., in the department of biochemistry of the University of Glasgow, the Scottish group of this society is to hold a symposium on Nutrition and the Liver. Prof. J. N. Davidson will be in the chair, and the speakers will include Dr. H. N. Munro, Dr. J. M. Naftalin, Dr. E. Kodicek, Dr. J. Waterlow, and Dr. A. L. Latner. Further particulars may be had from the secretary of the group, Rowett Research Institute, Bucksburn, Aberdeenshire.

Study Leave

Regional hospital boards and boards of governors have hitherto been allocated each year fixed sums to provide study leave for their staffs. The Minister of Health has reconsidered this arrangement and has decided that in future no annual maxima are to be laid down (HM[54]28). He proposes to review the arrangement after two years, and asks that meanwhile boards record the sums authorised.

Southend-on-Sea Hospital

Sir Francis Walshe, F.R.S., will deliver the first Sydney Body lecture on Wednesday, April 14, at the General Hospital, Rochford, at 8 P.M. He will speak on the Changing and the Unchanging Face of Medicine. After the lecture the first Sydney Body gold medal will be presented to Dr. William Evans for his work in cardiology.

British Council for Rehabilitation

The council is holding a residential course from April 12 to 14, in Liverpool, with the help of the extramural department of the University of Liverpool, on the Disabled—their Capacity for Work. The programme will include discussions on the Gastric Problem (speakers, Prof. C. F. W. Illingworth and Dr. J. N. Macdonald); Rehabilitation of Chest Conditions (Dr. A. Thelwall Jones and Dr. Peter Edwards); and the Cutaneously and Orthopaedically Disabled Worker (Dr. F. Glyn-Hughes and Mr. H. G. Almond). Further particulars may be had from the secretary of the council, Tavistock House (South), Tavistock Square, London, W.C.1.

Institution of Sanitary Engineers

On Tuesday, April 6, at 6 P.M., at Caxton Hall, Westminster, Dr. R. F. Guymer will address this institution on the Roles of the Doctor and the Engineer in Public Health.

Design of Animal Houses

The Laboratory Animals Bureau will hold a symposium on this subject at 1, Wimpole Street, London, W.1, at 10.45 A.M., on Thursday, May 6, under the chairmanship of Dr. H. J. Parish.

National Society of Children's Nurseries

This society is holding a conference on May 8 at County Hall, Westminster, London, S.E.1, on the Needs of the Family in a Changing Society. Further particulars may be had from the secretary of the society, 45, Russell Square, W.C.1.

Hospital Laundries

Mr. S. J. Whitaker has been appointed as a laundry engineer to the staff of the Ministry of Health, to advise on the efficiency, economical operation, and design of laundries and laundry plant in hospitals. He will also advise hospital authorities which may be considering reorganisation of their laundry services.

Dr. Ludwig Guttman has left London for Pakistan, where he is to advise the government on a rehabilitation programme for disabled ex-Servicemen.

Diary of the Week

APRIL 4 TO 10

Monday, 5th

INSTITUTE OF NEUROLOGY, The National Hospital, Queen Square, W.C.1

5 P.M. Dr. Bronson Crothers (U.S.A.): Extrapyramidal Disorders Due to Erythroblastosis.

Tuesday, 6th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1

5 P.M. Prof. D. M. Dunlop: Complications of Diabetes. (First of two Lumleian lectures.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1

8 P.M. Section of Pathology. Dr. P. A. Gorer, Mr. R. E. Billingham, D.Phil., Mr. W. J. Dempster, Prof. P. B. Medawar, F.R.S.: Immunological Problems of Tissue Grafting.

Wednesday, 7th

ROYAL SOCIETY OF MEDICINE

5.15 P.M. Section of History of Medicine. Dr. M. H. Draper: Sir Michael Foster. Sir Arthur MacNalty: Sir John Burdon Sanderson.

8 P.M. Section of Surgery. Prof. Ian Aird, Dr. T. Counihan, Prof. W. J. Hamilton, Mr. Norman Veall: Surgery of Conjoined Twins.

MANCHESTER MEDICAL SOCIETY

4.30 P.M. (Medical School, University of Manchester.) Section of Medicine. Dr. W. Brockbank: Treatment of Asthma with Cortisone.

YORKSHIRE SOCIETY OF ANAESTHETISTS

8 P.M. (General Infirmary, Leeds.) Prof. R. R. Macintosh: Experiences Abroad.

Thursday, 8th

ROYAL COLLEGE OF PHYSICIANS

5 P.M. Professor Dunlop: Complications of Diabetes. (Second of two Lumleian lectures.)

ALFRED ADLER MEDICAL SOCIETY

8 P.M. (11, Chandos Street, W.1.) Prof. W. O. W. Nixon, Mr. Norman Morris: Psychosomatic Reactions in Obstetrics and Gynaecology.

MEDICAL SOCIETY FOR THE CARE OF THE ELDERLY

10 A.M. (Queen's Hospital, Croydon, Surrey.) Dr. A. D. Thom-on. Dr. Francis Bach: Rheumatic Disease.

2 P.M. Dr. Trevor Howell: Problems of a Geriatric Unit.

SURREY INTER-HOSPITAL PSYCHIATRIC ASSOCIATION

7.30 P.M. (Long Grove Hospital, Epsom, Surrey.) Dr. D. J. Aderley: Cardiazol Treatment. Dr. A. B. Monro: Assessment of Psychiatric Cases.

ASSOCIATION OF CLINICAL PATHOLOGISTS

3 P.M. (Old Swan Hotel, Harrogate.) Opening of three-day meeting.

Friday, 9th

ROYAL SOCIETY OF MEDICINE

8.30 P.M. Dr. M. G. Candau: Role of W.H.O. in International Health Work.

BIOCHEMICAL SOCIETY

11 A.M. (Department of Biochemistry, University New Buildings, Edinburgh.) Scientific papers.

Saturday, 10th

SOUTH EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY

10.30 A.M. (County Hall, Maidstone, Kent.) Dr. E. R. Jones, Dr. Lynne Reid: In Circulation and Out.

4. Nakahara, W. *Gann*, 1926, 20, 13.

THE SECRETIONS OF THE BRAIN * RELATION OF HYPOTHALAMUS TO PITUITARY GLAND

S. ZUCKERMAN

C.B., M.A. Oxfd, M.D. Birm., D.Sc. Lond., F.R.S.

PROFESSOR OF ANATOMY, UNIVERSITY OF BIRMINGHAM

THE name of Thomas Addison, whom we commemorate in this lecture, separates the history of endocrinology into a past which his achievement left in deep shadow—so deep, indeed, that he is sometimes regarded as a symbol marking the beginning of the subject—and a present that goes on radiating the promise which the most significant of his studies revealed. His genius, which lay in an acute, accurate, and persistent power of observation, reached its fulfilment in the realisation that the symptoms and signs of the illness which bears his name are associated with disease of the adrenal glands. Most big discoveries in biological and medical science begin at the descriptive level, at the level of accurate observation, of discerning classification, and of useful correlation. It was in itself an achievement to generalise as a single syndrome the various signs and symptoms manifested by eleven different individuals. It required even more insight to suggest that the disease could be causally related to destruction of the suprarenal glands. From the point of view of modern science, however, the essential act of genius lay in the realisation that if this were so, something of the kind we now designate as a hormonal mechanism was at play. For there must have been some such idea in Addison's mind, even if his brief writings on the subject are anything but explicit on this point.

Emergence of the Concept of Hormonal Action

We need to remind ourselves that in 1849, when Addison first reported his observations, and in 1855 when he published his now classical monograph, there was no clearly stated concept of hormonal action. That emerged slowly during the latter half of the 19th century, as a result of the experimental studies of men such as Claude Bernard, E. Brown-Séquard, George Oliver, and Edward Schafer (later Sharpey-Schafer), and of the clinical observations of such physicians as Hilton Fagge, William Gull, and Addison himself. And it did not take the specific shape which it has today until 1904, when Bayliss and Starling elaborated the idea that the different tissues and functions of the body are coordinated by chemical messengers "speeding from cell to cell along the blood stream." "These chemical messengers or 'hormones,'" as Starling (1905) called them, "have to be carried from the organ where they are produced to the organ which they affect by means of the blood stream and the continually recurring physiological needs of the organism must determine their repeated production and circulation through the body."

Yet though this conception did not crystallise until the turn of the century, the epoch in which Addison was pondering the significance of his observations was far from devoid of ideas of some such mechanism. It may well be that he was unfamiliar with any of the 17th and 18th century writings which seemed to suggest—however vaguely—that there were such things as hormones. It may also be—in fact, it is almost certain—that he was unaware that in the very year in which he first reported his observations and his suspicion that the adrenal glands "may be either directly or indirectly concerned in sanguification" and with "the proper elaboration of the body generally, or of the red particles more especially," a young experimentalist of Göttingen, A. A.

Berthold (1849) had published a short paper in which he had not only reported that the transplantation of the testes of the cock to another part of the body prevented the normal changes of castration, but also correctly concluded that male secondary sexual characters and behaviour depend on some substance secreted by the testes into the blood. But even if he knew none of this, Addison must have known that his colleague T. Wilkinson King (1836) believed that the thyroid gland stored some material which, passing into the general circulation, exercised "important subsequent functions in the course of the circulation."¹ He also must have known about the experimental thyroidectomies and studies of the chemical nature of thyroid fluid made by his other colleague, Astley Cooper (1836). He could hardly have been surprised, therefore, that a year after the appearance of his own monograph, Brown-Séquard (1856a and b) showed that pigs, dogs, cats, rabbits, and mice died very rapidly when their adrenal glands were removed, and from this drew the conclusion that the adrenals elaborated some principle which was essential for life. He could not have been surprised, for the simple reason that although his discoveries were made before the dawn of the hormonal theory, as we know it today, they belonged to a period which had certainly not freed itself from the influences of an older theory of internal secretions. Wilkinson King thought in terms of such an hypothesis, as Brown-Séquard was still doing when, at the turn of the century, he sought to generalise his views on hormonal action, and in doing so merely restated the hypothesis which de Bordeu had put forward in 1775 (Brown-Séquard and D'Arsonval 1891; see also Rolleston 1936). Another whose mind flowed in similar channels was Jonathan Hutchinson (1856), surgeon of the London Hospital, who was among the few who set out to confirm and corroborate Addison's clinical analysis of adrenal insufficiency. In his little book on constitutional medicine Hutchinson (1884) clearly reveals that many of the conventional physiological conceptions of the 19th century took their origin from the old theory of the humours. Clearly these were still in the air when Addison pondered over the strange symptoms and signs of the patients whose adrenal glands had been destroyed by disease.

To say this in no way disparages Addison's share in the development of modern endocrinological concepts. Nor does it mean that there is no real distinction between the old and the new humoral theories. The old theory was formulated in a way which did not call for experimental verification. The new is a predictive or causal type of modern scientific hypothesis. The general proposition that it states demands test; and at the same time it reveals an endless vista of research which cannot but be fruitful both from the point of view of the content of pure knowledge, and from that of the aims of clinical practice. Yet there are parallels between the two kinds of theory. They reveal themselves clearly when we compare the difficulties into which 17th and 18th century physicians got themselves when they tried to explain how the presumed secretions of the brain pass to the pituitary with those which now beset us in our understanding of the functional relations of the latter organ to the hypothalamus.

1. "All living organs receive supplies of the circulating fluids, calculated to maintain their growth or secreting functions; and, in particular cases, other additional ingredients form essential parts of the materials on which the organs are destined to operate. Now, we find that the circulating fluids, with or without these superadded ingredients, are submitted to the actions of various organs, and to as many different modes of operation, each for its peculiar results" (King 1836). In 1840 George Gulliver suggested that the adrenal glands poured into the blood "a peculiar matter which has doubtless a special use."

* The seventh Addison Memorial Lecture, delivered at Guy's Hospital, London, on Dec. 16, 1953.

The Old View of the Secretions of the Brain

THE FOUR HUMOURS

Let us begin by recalling some of the central features of the old theory of the humours (e.g., see Singer 1925, Meyer 1937, Singer and Rabin 1946, Singer 1952). It derives from the Aristotelian concept that every material thing is made up of different proportions of the four common elements—earth, water, air, and fire—of which any one or two are dominant in every object. Each of these four fundamental essences or existences represented the union of two of four primary and opposite qualities (hot, cold, wet, and dry), and corresponding to them were the four fundamental humours—blood, phlegm (or pituita), yellow bile, and black bile (melancholia). When the four humours were in proper balance,

the body was healthy.

When one humour was unduly strong, illness resulted. The difference in the temperament and constitution of individuals was due to slight alterations in the balance of the humours or to a surplus of any one of them. An excess of black bile, insufficient to lead to manifest disease, produced the melancholic temperament; a non-pathological excess of phlegm or pituita produced the phlegmatic person; of blood, the sanguine temperament; and of yellow bile, the choleric temperament.

Fig. 1.—Vesalius's conception of the funnel (infundibulum) (B) through which the phlegm from the brain trickled into the pituitary gland (A). The four imaginary ducts C, D, E, F, carried the phlegm from the gland.

There was also the idea that while the four humours pervaded the body, and determined its state of health and the temperament or "complexion" (literally "weaving together") of the individual, each had its principal organ. Yellow bile or choler came from the gall-bladder, and black bile or melancholy from the spleen. Blood arose from the liver, and the brain was responsible for the phlegm or pituita, which escaped by way of the infundibulum of the third ventricle into the pituitary body, and thence along the olfactory nerves through the cribriform plate of the ethmoid into the nose.² Over and above all this, the Ancients realised that some tissues (e.g., the testes) endowed the body with particular humours or particular qualities.

PRODUCTION OF CEREBRAL HUMOUR

One of the more useful discussions regarding the cerebral humour is provided by Swedenborg in a posthumous monograph published³ for the first time in 1882, 140 years after his death.

"For the purpose of preparing the blood," Swedenborg wrote, "the soul has established in the cerebrum an illustrious chymical laboratory, which it has arranged into members and organs and by the ministry of these it distills and elaborates a lymph animated by the animal spirit, whereby it imbues the blood with its own inmost essence, nature, and life."

Two spirits were produced: one, "the animal spirit or the nervous force," which is elaborated in the glandules of the grey substance" (i.e., in the Pacchionian bodies), and contained within the individual nerve-fibres of the

cortex; and the second, a nervous juice which exuded from the capillaries and circulated between the nerve-fibres.

PASSAGE OF CEREBRAL HUMOUR TO THE PITUITARY

Like others before him, Swedenborg was exercised about the way in which the essential spirit so formed, or pituita, left the brain. Thomas Willis (1664) had argued that "the position and structure" of the infundibulum indicate that

"some humour out of the ventricles of the cerebrum is carried into the pituitary gland. For that part is so constituted, that a discharge of humours is effected into its aperture from every angle and recess of the interior cerebrum, and its appendage; and while in the various animals the shape and the situation of the ventricles differ, nevertheless in every one of them all the ventricles, of whatever kind they be, have apertures opening in the direction of the infundibulum."

Willis felt that

"there was no room for doubting, that serous liquids descend by this way from the cerebrum into the pituitary gland. . . . If any one takes but a cursory view of the parts which are situated around the ventricles, and if he examines their structure but lightly, he will easily agree with the Ancients, that the excrements of the cerebrum are discharged partly through the infundibulum into the palate underneath, or that in an anterior direction they are cast out through the olfactory bulbs into the nares."⁴

Tied to the idea that there had to be some connection of this kind, Swedenborg also had no doubt about it, in fact, existed.

"The infundibulum," he wrote, "is not only a *vas deferens* or an excretory duct, but it is also a *vas secernens* or a secretory vessel; for those things which in the ventricles have become mixed up, thickened, and in a certain extent amalgamated, the infundibulum separates and filters; . . . [one part] it instills by a fibrous channel immediately into the substance of the gland; the latter it relegates around the gland, between the sides of the sella turcica."

He realised that the "highly liquid and refined alcohol of animal nature" about which he spoke was "utterly beyond the ken of the senses," but at the same time he felt certain that not only did the "enclosed moisture" of the infundibulum get into the pituitary, as described, but that the infundibulum also transmitted to the pituitary gland "a genuine and fresh spirit of its own."⁵

The invisible opening from the infundibulum into the pituitary, about which Swedenborg had no doubts, disturbed others, and one or two tried to find out experimentally whether, in fact, it existed—as theory demanded that it should. So it was that Vieussens (1685) injected a coloured alcohol into the third ventricle. He found that the fluid passed through the infundibulum and stained the upper and lateral parts of the gland, but that it did not dye its interior. Dismayed though he no doubt was by the lack of a canal or "sensible perforation" in the lower part of the infundibulum, he nevertheless had to

4. Willis's own text has been consulted, but the translation is that of Tafel, Swedenborg's editor. Richard Lower (1631-1690), Willis's pupil, rejected this teaching, and believed that "whatever serum is separated into the ventricles of the brain and tissues out of them through the infundibulum to the glandula pituitaria distills not upon the palate but is poured again into the blood and mixed with it" (see Rolleston 1930).

5. ". . . a copious fibre descends into this organ [the pituitary gland] from the fornix and the centrum ovale—it enters into the pituitary gland itself, and infuses into it the spirit it derives from its origins, that is, from the cortical substances, and thereby it restores and vivifies the older spirit, or that which arrives in the passages between the fibres." After further speculation about the interaction of the two types of fluid or humour which enter the pituitary, Swedenborg continues: "This chymical operation which is accomplished in the infundibulum and finally in the pituitary gland, may be called not only a secretion and purification, but also a rectification and alcoholisation."

2. Vesalius (see Singer 1952) did not accept this view. He believed that channels passed on each side from the pituitary to the superior orbital fissure and foramen lacerum. (See fig. 1.)

3. Together with numerous annotations by R. L. Tafel, the editor of this posthumous work.

conclude that the latter was probably "furnished with loose pores and to consist of a substance which is highly fitted for the reception of a certain aqueous humour and for excreting the same again."

A few students appear to have followed a different path in their researches into this question. One was Lieutaud, professor of medicine in the University at Aix, and a foreign member of the Royal Society of London.⁶ His observations about the pituita are no more than a historical curiosity; but those he made about what we now know as the hypothalamo-hypophysial connection are extremely interesting. For it so happens that in the course of his studies he stumbled on what is called today the pituitary-portal system of veins.

VESSELS OF THE PITUITARY STALK

The record of this discovery is in a volume that was published in 1742 under the title *Essais Anatomique*—essentially a general textbook of anatomy. Its fifth section deals with the central and peripheral nervous system, and in his description of the third ventricle of the brain Lieutaud drew attention to a deep fossa anteriorly whose aperture gradually narrows as it approaches the base of the pituitary stalk. According to Lieutaud, the stalk, contrary to usual belief, is not canalised, but instead is a kind of cylinder "two to three lines" thick, formed of a grey substance, and covered by pia mater. On the other hand, running along it are very small longitudinal vessels which communicate with those of the pituitary gland below.⁷

Hardly ten years had passed before this observation, as well as Lieutaud's general views about the functions and secretions of the brain, were attacked by Théophile de Bordeu, the physician to whom we owe the first fairly clear conception of humoral action.⁸ For Lieutaud the

6. He was elected in 1739, the same year as his more renowned fellow-countryman, Buffon.

7. "La tige, qui s'éleve de la glande pituitaire, répond véritablement à la partie la plus profonde de cette fosse : mais elle n'a point de cavité, comme on le prétend ; c'est une espece de cylindre de deux ou trois lignes de hauteur, formé par la substance cendrée, et recouvert de la pie-mere. On remarque de très-petits vaisseaux qui marchent dans son axe, communiquant avec ceux de la glande qui reçoit cette colonne ou qui la soutient. J'ai donné à cette partie le nom de *tige pituitaire*, parce que j'ai crû que celui d'entonnoir ne sauroit lui convenir. Il n'est point difficile de montrer la solidité de la tige pituitaire, j'en donnerai la manière dans l'administration"—which he does in the chapter which follows.

8. The concept is outlined in the sixth part, entitled "Analyse Médicinale du Sang" of his volume *Recherches sur des Maladies chroniques*, first published in 1775. de Bordeu held that the different organs were related to each other through the spongy cellular tissues of the body, and that in this way the "humours" of one organ were able to influence the functions of another. de Bordeu particularly emphasised the effect of testicular and ovarian secretions; and the fact that the gonads in some way control the development of secondary sexual characters and behaviour. While one should not deny de Bordeu the distinction of having provided an indication of hormonal action, it would be an exaggeration to say that his writings reveal the precise formulation of hormonal action as understood today.

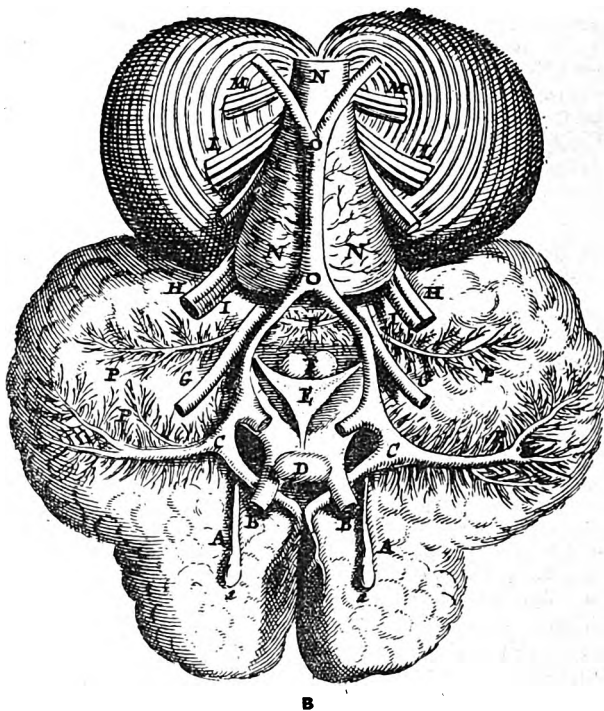

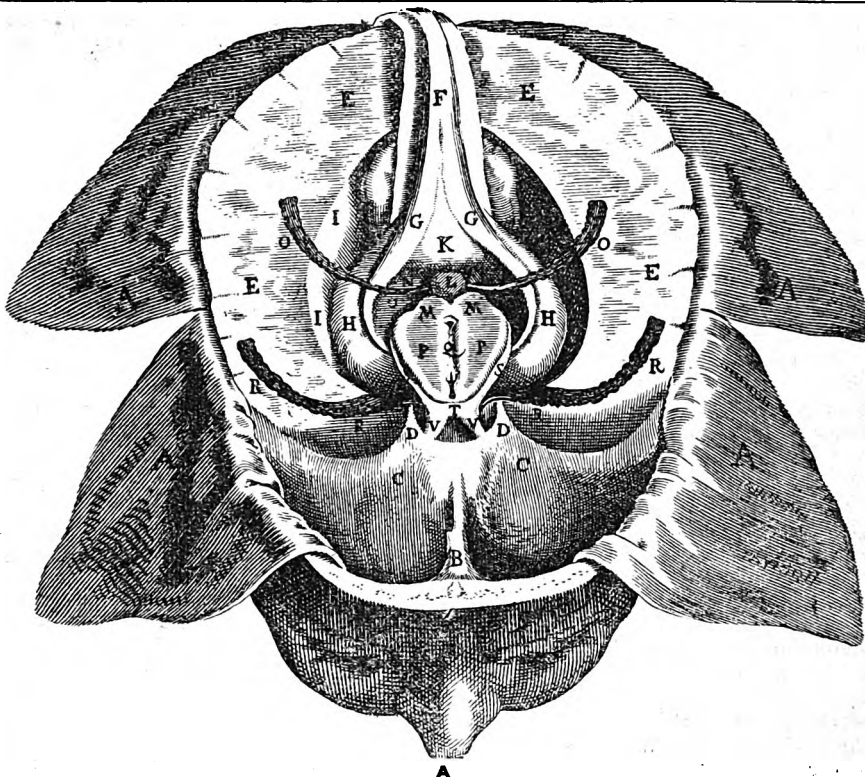

Fig. 2—Riolan's diagrams showing the pathway of the pituita from the third ventricle to the pituitary.

- (A) View, from above, of horizontal section of brain. P, ? Thalamus. M, ? Superior quadrigeminal body. L, Pineal gland. [T, Optic chiasma. V, Optic nerves. Q, "The bottom of the third ventricle in which behind is the hole likened to the fundament; it tends to the beginning of the marrow of the back; before it is the hole compared to the womb, and is carried to the funnel." (Culpepper's translation of Riolan's legend.)
- (B) The base of the brain. B, The optic nerves. D, Pituitary gland. E, Infundibulum or funnel. F, "The protuberances of the brain, set before the passage which carries the phlegm to the funnel"—i.e., the mammillary bodies. N, Brain-stem.

problem of the brain was simple. In designing it Nature had three purposes, and three only: (1) to provide, as it were, a scaffolding for the blood-vessels of the brain; (2) to provide a structure in which the life spirit could be separated out; and (3) to provide an adequate reservoir for this spirit. Would not, he asks, a porous, palpable, or simple spongy mass of moderate density satisfy these requirements? Why, he asks, search further in order to understand the nature of the brain, a secretory organ whose main function is to separate the extremely fine molecules of the ethereal liquid which is the animal spirit? And as for the cerebral nerves, are they not the channels by which this spirit courses from the brain to all parts of the body?

de Bordeu delivered his criticism in 1751. His main theme was that the glands of the body release their emanations as a result of some intrinsic action, in certain circumstances augmented by local irritation or shaking of the body, and not as a result of compression by neighbouring muscles or organs. He devoted a large part of his discussion to the widely held belief that the brain is a glandular organ, and that some vital spirit is directed along the nerves. In the course of his statement, in which he indicates quite clearly that he was no supporter of these views, de Bordeu points out that the three functions which Lieutaud attributed to the brain as a glandular organ could just as well have been applied to almost any organ or tissue of the body. The vital spirit, he remarks, is always shaped by the particular fantasy of the person writing about it; and the arguments of those who are convinced that the brain distills such spirits, or that the nerves, and particularly the olfactory nerves, are a channel for the passage of some cerebral distillation, are no more probable than the opinions of those who deny them.

de Bordeu was equally unimpressed with Lieutaud's view that the solidity of the pituitary stalk can be easily demonstrated by cutting it in successive sections. The stalk, he found, is too delicate, and is only crushed and torn by such treatment. He admits, however, the existence of axial vessels along the stalk, and in doing so leaves the impression that in describing them Lieutaud had implied that they were a channel for the humours of the brain to the pituitary. de Bordeu also states that Riolan⁹ had long before noted the same vessels, and that he, too, had regarded them as a pathway for the pituita (see fig. 2).¹⁰ Finally, he was unconvinced by Lieutaud's assumption that the axial-stalk vessels communicate with those of the pituitary gland. The ventricular injections which he made to determine the nature of the connection between the base of the brain and the pituitary being indecisive, he ended by emphasising the urgent need for new researches to find out whether the infundibulum was indeed the excretory canal of the brain.

As we now know, Lieutaud and de Bordeu were both right and wrong. de Bordeu was wrong and Lieutaud right in suggesting that the axial-stalk vessels communicate with those of the pituitary below; while de Bordeu was well justified in attacking Lieutaud's conception of the structure and function of the brain, and in doubting that a vital fluid flows from the base of the brain to the pituitary.

ECLIPSE OF THE HUMORAL THEORY

The point is that while he was one of the architects of the modern theory of hormones, de Bordeu was a never-tiring opponent of the old humoralism (see Cumston

9. Jean Riolan the younger (1577-1657).

10. The passage in question occurs in Riolan's *Enchiridium Anatomicum et Pathologicum*, first published in Paris in 1648, and translated into English in 1657. The reference is, however, hardly precise; all that Riolan says is that there are four minute channels on the infundibulum through which some "serum" is distilled on to the palate and fauces.

1926). His controversy with Lieutaud was inspired less by any fundamental disagreement with the latter's anatomy (which, for its period, was far from bad) than by opposition to his attempt to interpret anatomical observations in terms of an outworn dogma. Those who believed in the old humours had to find a route by which the pituita escaped from the brain—whether through the stalk which connected the infundibulum and the pituitary, or by way of vessels along the stalk. Those who did not were suspicious of the whole idea that something passed from the brain to the pituitary. The eclipse of the old humoral theory—the end to which de Bordeu had turned so many of his energies—was finally due to the increasing use of experiment in medicine during the 17th century (following Harvey's great discovery of the circulation), and to the emergence of the cellular theory of bodily processes and disease in the 19th century. Morgagni, whose labours all but filled the 18th century, showed that diseases could be classified according to the parts of the body in which their symptoms occurred, and that it was reasonable to explain them by reference to the associated anatomical changes. His underlying theme was that disease is due to pathological change in specific organs, and not to an imbalance of humours which affect the whole body. From organs it was a relatively short step to the cells and tissues by which they are constituted. In the end it was the cellular theory, the triumph of which we owe to Virchow, and the bacterial theory as developed by Pasteur, Koch, and Lister, which displaced the older humoral theory of disease.

As the old humours disappeared, so too did the need to establish a specific pathway between the pituitary and the third ventricle. And thus it was that the axial-stalk vessels of Lieutaud dropped from view. But the question of a tubular connection between the infundibulum and pituitary continued to exercise successive generations of anatomists. Vieussens's experimental injection of a dye into the third ventricle, which had been repeated by de Bordeu in 1751, was tried again by the brothers Wenzel (1812). During the period 1796-1800 they performed twelve experiments on the human brain, and concluded that when any suitable liquid is injected into the third ventricle nothing passes into the infundibulum, and further that the latter is more closely joined to the posterior than to the anterior lobe of the hypophysis.

This last observation foreshadows what we know today—that whatever the connection between the hypothalamus and the pituitary, it is much more intimate in the case of the posterior than of the anterior component of the gland. Wenzel also observed vessels, connecting the pituitary with the infundibulum, which may well have been the same channels as are now called the pituitary-portal system of veins, and which Lieutaud originally described. So, too, did Luschka, who in 1860 described what we might now recognise as the primary capillary loops of the pituitary-portal vessels.

"Here and there," he writes, "the vessels bulge out, and in the form of loops which are arranged in various ways, they make their way into the interior of the infundibulum, and sometimes their number is so great, that they alone constitute a loose, red substance in the interior . . . By these vascular loops and the productions which result thence, not only the cavity of the infundibulum is obstructed, but also the proper substance of this organ is crowded out and broken up."¹¹

He also speaks of "blood vessels which run in a longitudinal direction, and which not infrequently are enlarged in the fashion of aneurisms."

Luschka, it should be noted, was quite certain that as a rule "the infundibulum has an aperture only in its upper extremity and in that portion which communicates with the tuberculum cinereum . . . Only in exceptional cases the cavity of the infundibulum can really be traced into the pituitary gland." He also appears to have had a remark-

11. The translation is that of Tafel.

ably clear understanding of the anatomical relationship of the tuber cinereum, the infundibulum, and the posterior lobe of the gland. They were, he realised, parts of the same anatomical complex, possessing fundamentally the same finer structure.¹² Even more striking was his observation that "fine nerve tubes" passed from the infundibulum into the posterior lobe, where they became varicose and broke up. This achieves a particular significance in the light of new discoveries, to which I shall shortly refer, over the past few years, which resurrect, to mystify us once again, the problem of how the brain controls the functions of the pituitary.

(To be concluded)

VARICOSE VEINS COMPARISON OF THE STRIPPING OPERATION WITH OTHER METHODS OF TREATMENT

J. F. BOLTON CARTER

M.Chir. Camb., F.R.C.S., M.R.C.P.

ASSISTANT IN THE SURGICAL UNIT, UNIVERSITY COLLEGE
HOSPITAL MEDICAL SCHOOL, LONDON

THERE have been many recent reports on the treatment of varicose veins, but few in which the results have been assessed after an adequate follow-up (Hodge and Grimson 1945, Mahorner and Ochsner 1938, Mathiesen 1953).

In 1949 an attempt was made to follow up all the cases of varicose veins that had been operated on in the surgical unit at University College Hospital between 1942 and 1948. Owing to the war, there were only 81 cases; of these, 48 were traced and reviewed. 15 were males, and 6 of these had recurrence necessitating further treatment; of the 33 females, 11 required further operative treatment and 16 required further injections. The patients had been treated originally by interruption of the saphenous vein and its tributaries at the saphenofemoral junction with, in some cases, further interruptions lower down the course of the vein and retrograde injections of ethamoline oleate or sodium morrhuate. None had been adequately followed up after operation.

In view of these findings it was decided to organise a follow-up clinic and attempt to compare the results of various forms of treatment. The choice of treatment of each case was left to the surgeon who did the operation; some surgeons did not approve of the more drastic procedures of stripping and excision. All the cases, however and by whomsoever they were treated, have for the last three years been followed up, at regular intervals, by one person. In this way assessment of the various forms of treatment in an unselected group of cases has been possible.

Classification

In order to compare results, the cases have been divided into three groups according to the severity of the condition:

Group I: uncomplicated varicose veins.—In this group the symptoms consisted in no more than aching and slight swelling of the ankles, and the signs of no more than demonstrable superficial varicosities, with or without œdema after long standing but with no evidence of skin changes.

12. "The fundamental substance of the infundibulum is really a soft, reddish grey mass which on the one hand is continued into the tuber cinereum, and on the other into the posterior lobe of the gland . . . But it must be well observed that the nervous substance properly constitutes neither the infundibulum nor the posterior lobe of the gland, to any great extent; and that the substance of said lobe consists essentially of a growth of connective-tissue ingredients and of epithelial elements. These ingredients gain the upper hand more and more, and the nervous elements grow less and less, the nearer the infundibulum approaches the pituitary gland." (Translation taken from Tafel.)

Group II: complicated varicose veins.—In this group were included all those with a past history or present signs of ulceration, eczema, or superficial phlebitis, but without a history or evidence of deep venous thrombosis.

Group III: varicose veins secondary to deep venous thrombosis.—In this group were included all cases in which there was a past history of deep venous thrombosis or in which investigation showed incompetence of the deep venous system.

The various forms of treatment were as follows:

Injection alone.—In the majority of cases ethamoline oleate was used, but a very few were treated with sodium morrhuate. Those cases in which there was no evidence of retrograde flow were treated in this manner.

Groin tie alone.—"Groin tie" implies interruption of the long saphenous vein and all its tributaries at the saphenofemoral junction.

Groin tie and injection.—All the cases treated by groin tie (with or without ties lower in the course of the vein) together with injection of sclerosant fluid by retrograde catheterisation or needle at the time of operation are placed under this heading.

Stripping and excision.—This operation included interruption of the saphenous vein and all its tributaries at the saphenofemoral junction, stripping out of the saphenous veins with interruption of the communicating vein between the long and short systems, and excision of those veins in the calf which were too tortuous to permit the passage of the stripper: in short, ablation of all visible and palpable superficial varicosities.

Short saphenous tie alone.—Interruption of the short saphenous vein in the popliteal fossa.

Lower tie or ties.—Interruption of superficial varicosities, without interruption of the long saphenous vein at the saphenofemoral junction. This operation was occasionally done under local anaesthesia in patients whose general condition or age did not warrant more major procedures.

Physiotherapy.—All patients with ulceration were given massage, surging faradism, and Bisgaard (1948) type bandages; and they wore elastic stockings afterwards until the skin was soundly healed and œdema controlled. All patients with a past history of deep thrombosis with skin changes or œdema were similarly treated.

Grafting.—Cases with ulceration in which healing was unduly slow, despite physiotherapy and bed rest, were treated by split-skin grafting.

Assessment of Results

Although the follow-up period has been no more than three years, this seems enough for a first assessment; and it is hoped that these cases will again be assessed after a further five years. The assessment has been made by dividing the results into five classes as follows:

1st class.—No symptoms or signs of varicosities in the limb, no injections required.

2nd class.—No symptoms, but an injection required at not less than six-monthly intervals for minimal recurrences.

3rd class.—No symptoms, but injections required at two-monthly or three-monthly intervals to keep the recurrences in check.

4th class.—Recurrent or remaining symptoms, and requiring repeated injections.

5th class.—Recurrent ulceration, eczema, or incompetent varicosities requiring further treatment other than injection.

GROUP I: UNCOMPLICATED VARICOSE VEINS

This group comprised 124 patients (55 males, 69 females); 68 had bilateral varicosities, making a total of 192 limbs for therapy. 22 of the patients had had previous treatment as shown in table I.

TABLE I—PREVIOUS TREATMENT ELSEWHERE OF 22 PATIENTS
IN GROUP I

Type of treatment	No. of patients
Unilateral groin tie	7
Bilateral groin tie	5
Local tie and injection	3
Injection	6
Elastic stockings	1

TABLE II—GROUP I (UNCOMPLICATED VARICOSE VEINS):
TREATMENT AND RESULTS

Type of treatment	No. of limbs	Assessment of result (class)					
		1st	2nd	3rd	4th	5th	No assessment

Groin tie alone ..	17	1	5	4	0	4	3
Injection alone ..	8	0	0	2	4	2	0
Lower tie or ties ..	4	1	1	1	0	1	0
Short saphenous tie alone ..	1	1	0	0	0	0	0

86 patients complained of aching in the legs, and 16 of œdema of the ankles, at the end of the day: 9 sought operation for cosmetic reasons; while 29 had no symptoms.

Of the 124 patients treated, 68 are still attending the follow-up clinic, 52 have defaulted, and 4 have not once attended. The average length of follow-up of those still attending is thirty-two months. The average length of follow-up of those defaulters who have been assessed is twenty-two months. No assessment was made on 40 limbs since the patients had not attended for long enough to warrant this. The types of treatment and assessment of results are shown in table II.

Complications

Associated with operation.—All the patients who were treated by the stripping procedure had a postoperative course of penicillin for five days and were made to walk about on the day after operation. There were no serious complications of operation. 1 patient developed a hæmatoma in the groin on the day after operation; this was evacuated. 1 patient had the right saphenous nerve damaged in the calf by a stripping operation; a patch of anæsthesia, the size of half a crown, developed just below the medial malleolus, and this took nine months to recover.

During follow-up.—In 1 patient spontaneous superficial phlebitis developed. In another patient popliteal thrombosis developed the day after an injection of 1.5 ml. of ethamoline oleate in the calf; this was treated by

Unilateral groin tie, ulcer excision, and graft ..	1
Injection	1

physiotherapy and a supportive bandage. There was 1 case of severe ethamoline sensitivity with glottic œdema.

GROUP II: COMPLICATED VARICOSE VEINS

There were 66 patients in this group (26 males, 40 females); 47 had bilateral varicosities, making a total of 113 limbs for therapy. 15 of the patients had had previous treatment as shown in table III.

The numerous symptoms and signs in this group are shown in table IV. 8 of the patients in this group were investigated by phlebography (5 descending, 3 ascending). 2 were investigated by measurement of the venous pressures (Longland and Walker 1950). These investigations were undertaken to prove the competence of the deep venous system.

Of the 66 patients in this group, 43 are still attending the follow-up clinic, 20 have defaulted, and 3 have never been seen since discharge from hospital. The average length of follow-up of those still attending is thirty-five months. The average length of attendance of those defaulters who have been assessed is twenty-six months.

No assessment was made on 24 limbs, as the patients had not attended long enough to warrant this. The types of treatment and assessment of results are shown in table V. The results of physiotherapy and grafting have not been assessed, as in nearly all cases they were combined with other forms of therapy.

Complications

Associated with operation.—1 patient had a small area of anæsthesia owing to damage to the long saphenous nerve; this took two years to recover. There was 1 case of postoperative hæmatoma in the groin; and 1 patient developed multiple stitch abscesses eight weeks after discharge from hospital. 1 patient treated by groin tie alone had transient but definite postoperative œdema of the leg which was considered to be due to deep thrombosis; this was rapidly relieved by physiotherapy.

During follow-up.—There were 2 cases of popliteal thrombosis following injections of 1.5 ml. of ethamoline in the back of the calf; there was 1 injection ulcer due to extravenous ethamoline, which took a long time to heal. 1 patient was intolerant to both ethamoline oleate and sodium morrhuate (pain in the back and vomiting).

TABLE IV—SYMPTOMS AND SIGNS IN GROUP-II CASES

Symptoms and signs	No. of patients
Past unilateral ulceration	20
Past bilateral ulceration	6
Present unilateral ulceration	14
Present bilateral ulceration	2
Unilateral eczema	21
Bilateral eczema	2
Unilateral superficial phlebitis	14
Bilateral superficial phlebitis	4
œdema of ankles	16

There were 2 recurrent ulcers, 3 cases of recurrent eczema, 2 cases of recurrent superficial phlebitis, and 1 case of spontaneous popliteal thrombosis in a labourer, apparently after climbing a ladder. Of the 3 cases treated by stripping and excision and assessed in the 5th class, 2 had recurrent eczema, and the 3rd a very ugly redilatation in the popliteal fossa, where the short saphenous vein had been inadequately stripped. There were no cases of recurrent ulceration following stripping.

GROUP III: VARICOSE VEINS SECONDARY TO DEEP THROMBOSIS

There were only 17 cases in this group (3 males, 14 females); in 4 there was a history of bilateral thrombosis, and there were thus 21 limbs for therapy. Previous treatment had been as follows: 1 patient had had a superficial femoral ligation and graft, followed by lumbar sympathectomy and further graft; another had had the groin explored and the veins tied twice and been grafted twice; and a 3rd had had a course of injections.

Phlebography was done in 8 of the cases (descending 5, ascending 3). The venous pressures were measured in 2 other cases.

The symptoms and signs of the cases in this group are shown in table VI, the types of treatment and the assess-

TABLE V—GROUP II (COMPLICATED VARICOSE VEINS):

ment of the results in table VII. 15 of the patients have continued to attend the follow-up clinic, while 1 has defaulted and 1 has never been seen since leaving hospital. Assessment of results of therapy has been made on 12 limbs, the average length of follow-up of these being thirty months.

All the patients with oedema or skin changes had a course of physiotherapy, and all were advised to wear supportive stockings until the oedema had been controlled completely for six months; several were advised to wear them permanently. In 1 case, associated with severe bursting pain, the pain was relieved by a superficial femoral tie, but the oedema of the leg rapidly returns if he gives up wearing an elastic stocking. Another patient was given a course of heparin for severe bilateral superficial phlebitis.

Complications

The only complication of operation was 1 groin hæmatoma. There have been 4 cases of recurrent ulceration, seen at follow-up: in 2 of the cases treatment had been by physiotherapy alone, and in the other 2 by injection and physiotherapy.

Discussion

Comparison of the various forms of treatment in groups I and II (table VIII) shows that the stripping and excision has been the most effective method. Of 82 limbs with uncomplicated varicose veins treated by stripping and excision, 50 (61%) have remained free from any sign of recurrence for a follow-up period

TABLE VII—GROUP III (VARICOSE VEINS SECONDARY TO DEEP THROMBOSIS): TREATMENT AND RESULTS

Type of treatment	No. of limbs	Assessment of result (class)

averaging twenty-seven months, and these have not required a single postoperative injection.

175 limbs have been treated by stripping and excision, with no serious postoperative complications such as thrombosis, infarction, or sepsis. In the past it was said that this procedure, owing to the associated mortality and morbidity, was not justified, and that the less drastic procedures, if not quite as effective, were safer. This criticism is without foundation under present-day conditions, provided that sepsis is prevented by the routine administration of an antibiotic, early ambulation is instituted, and the operating time is not unduly long. In bilateral cases the operating time can be considerably shortened by two surgeons working at the same time.

In this series the complications from the injection of sclerosants in the follow-up clinic have been more serious

than the immediate postoperative complications. 3 patients have suffered a popliteal thrombosis after an injection of 1.5 ml. of ethamoline oleate into varicosities in the back of the calf, despite the application of a tourniquet to the back of the knee; in 1 patient an indolent ulcer developed after an extravenuous injection of sclerosant; there have been 2 unpleasant cases of allergy. In the same group of cases only one serious complication of operation was seen—a deep thrombosis following a groin tie. The results in all three groups (see tables II, V, and VII) confirm that injection treatment is disappointing and recanalisation soon ensues. Kinmonth (1948) has demonstrated that any valves present at the site where sclerosant is injected are destroyed, and, if the vein is later recanalised, incompetence is bound to be present at the site of recanalisation and also in the communicating veins in the immediate neighbourhood. The potential dangers of retrograde injection of sclerosing solutions by

TABLE VIII—COMPARISON OF RESULTS OF TREATMENT

catheter are well known (Atlas 1943, Boyd and Robertson 1947). In this series it has been shown that a thorough stripping operation by ablating the veins reduces the rate of recurrence, and thus also reduces the necessity for postoperative injection of sclerosants.

Of 207 patients whose names were originally entered in this follow-up, 81 have defaulted and failed to attend when written for and given a further appointment—this despite the fact that all were warned that their varicosities would recur if they did not attend regularly for a check. With a condition such as varicose veins, in which the symptoms are usually trivial until complications arise, there will always be some defaulters; it is therefore reasonable to apply initially that form of therapy which is least likely to be followed by recurrence.

This follow-up has shown that stripping and excision, or ablation, of varicose veins is a safe procedure; 175 limbs have been treated in this way without serious morbidity. The disappointing and sometimes dangerous results of the injection of sclerosants have been demonstrated. Ablation has reduced the necessity for such injections and has, in this series, given better results than other methods of treatment.

Summary

The results of various methods of treatment of varicose veins have been assessed in 207 patients followed up for approximately three years.

Complete ablation of the veins by stripping and excision was done on 175 limbs without any serious complications.

This method was the most effective of those studied.

I wish to thank Prof. R. S. Pilcher for his advice in the preparation of this paper.

TWO-GENERATION PYLORIC STENOSIS

C. O. CARTER

B.M. Oxf'd, M.R.C.P.

GENETICS RESEARCH FELLOW

B. W. POWELL

M.B. Camb., M.R.C.P.

CONSULTANT PÆDIATRICIAN, PETERBOROUGH; LATE ASSISTANT
TO THE NUFFIELD PROFESSOR OF CHILD HEALTH*From The Hospital for Sick Children, Great Ormond Street,
London*

Rammstedt described his operation for congenital pyloric stenosis in 1912. It was first used at The Hospital for Sick Children, Great Ormond Street, in 1917 and an increasing number of successful operations were done there from 1918 onwards. The figures for 1918-25 are shown in table I.

Before then relatively few children were admitted to the hospital with this condition, and most of these died

TABLE I—TREATMENT AND NUMBER OF SURVIVORS OF CHILDREN WITH PYLORIC STENOSIS 1918-25

Years	Rammstedt's operation		Medical treatment		Total	
	Survivors	Dead	Survivors	Dead	Survivors	Dead
1918-19	6	14	1	6	7	20
1920-21	25	26	4	14	29	40
1922-23	55	18	0	6	55	24
1924-25	72	15	0	1	72	16

in hospital. It is natural therefore that, until recently, it has been most unusual to find children with pyloric stenosis one of whose parents also had well-documented pyloric stenosis. Caulfield in 1926 reported a mother and 2 children affected. But operation on both parent and child was first reported by Ashton (1929), the child having had Rammstedt's operation and the mother a gastro-enterostomy—though in the mother's case it was not recorded whether a tumour was found. Even in a very large series such examples have been rare (McKeown et al. 1951). Similarly there were no examples of proved pyloric stenosis among the parents of the 480 children treated between 1943 and 1947 at The Hospital for Sick Children, though Carter and Savage (1951) found that on two occasions a father was reputed to have had the illness. Since then it has been found that the mother of 1 child in the series described by Carter and Savage had the disease and was medically treated in The Hospital for Sick Children from the age of 8 to 20 weeks in 1912. The contemporary notes show that the diagnosis was not in doubt, a tumour being distinctly felt. The infant made a good recovery and has since had by her first husband 1 child with pyloric stenosis, confirmed at operation at another hospital, and by her second husband 2 children with pyloric stenosis confirmed at operation at The Hospital for Sick Children (fig. 1).

Another most interesting family, comprising a father, two sons, and a nephew, all proved affected, has been reported by Fenwick (1953). The father's condition was confirmed at operation at the age of 39, after 10 years of dyspepsia; as far as could be discovered this man had had no symptoms of the condition in infancy.

Since 1947, however, among the hundred or so children treated each year by Rammstedt's operation at The Hospital for Sick Children there have, except in 1949, always been one or two with a parent who also had pyloric stenosis confirmed at operation. There were 2 such children in 1948, none in 1949, 2 in 1950, 1 in 1951, 1 in 1952, and 3 in 1953 up till August (figs. 2-10). Of

these parents 5 underwent operation at The Hospital for Sick Children (figs. 2-4, 8, 10) and 1 at St. Thomas's Hospital (fig. 6); and their contemporary records are available. The other 3 were, according to the family, treated by members of the staff of The Hospital for Sick Children at London nursing-homes. The contemporary records are not now available, but all 3 have a characteristic abdominal scar.

Obviously in the parents of index cases the proportion affected is likely to increase steadily as more and more successfully treated children grow up. But in the children of index cases the proportion affected is likely to alter less. An estimate of this proportion is of greater value in fixing the mode of inheritance, as well as being a practical aid to diagnosis. In order to get a first approximate estimate of this proportion we attempted to trace from their original addresses all the 358 (299 male and 59 female) individuals who survived operations between the years 1920 and 1929 at The Hospital for Sick Children and St. Thomas's Hospital. In this way 85 (73 male and 12 female) were traced, of whom 28 (22 men and 6 women) had married and started their families and 9 were dead. None of the remaining 273 (226 male and 47 female) were traced from their original address, although 2 were known because they had already brought an affected child to hospital and 4 more because they brought an affected child to the hospital after the attempt to trace them had failed.

This gives two independent estimates of the proportion of children affected—one from the men and women traced from their original addresses, the other from those not so traced. The "traced" series is small, but the exact number and state of the children are known. The "untraced" series is larger, but the total number of children born to these men and women is not known and their affected children are known only if the child was brought to The Hospital for Sick Children or to St. Thomas's Hospital.

Data on the families of the 28 "traced" individuals who have children are summarised in table II, and the two families with an affected child are shown in figs. 11 and 12.

In these twenty-eight families it will be seen that of the 25 boys, 3 have had pyloric stenosis and Rammstedt's operation. These three operations took place at London hospitals, but not at The Hospital for Sick Children or

TABLE II—CHILDREN OF "TRACED" INDEX CASES WITH PYLORIC STENOSIS CONFIRMED AT RAMMSTEDT'S OPERATION IN 1920-29

Index case		Sons		Daughters	
Sex	No.	Affected	Normal	Affected	Normal
Men ..	22	2	19	0	18
Women ..	6	1	3	0	3
Total ..	28	3	22	0	21

St. Thomas's Hospital, and contemporary notes were available for all 3. Of the 21 girls none had pyloric stenosis treated by operation. This "traced" series is small, but it leaves little doubt that the proportion of sons of index cases with definite pyloric stenosis is well above the proportion affected in the general population. In addition to the children with proved pyloric stenosis 1 girl had projectile vomiting and some failure to gain weight and was successfully treated by the general practitioner with atropine methonitrate ('Eumydrin'); 1 boy and 1 girl had the same symptoms but required no treatment; 1 girl had projectile vomiting but no failure to gain weight and required no treatment. This association between suggestive symptoms and confirmed pyloric stenosis in the parent-child relationship is seen too in

other family relationships—for example, in the family reported by Cockayne (1938). It is natural to suggest, as Cockayne did, that "pylorospasm" represents a milder manifestation of the genetic factors predisposing to

pyloric stenosis, but it is not yet possible to be certain that this is so.

From the second series—the 273 men and women who were not traced from their original address—there is good confirmation of the view that the children of index cases have an increased risk of developing pyloric stenosis. The number of children they have had is, of course not known, but from the 1951 1% sample census (Census 1952) it may be estimated that the number will by now be roughly 150, more or less equally divided between sons and daughters.

From table i.1. of this report it is possible to estimate the proportion of men and women in Britain in each year of age who have been married for a given number of years. From table x.5. it is possible to estimate the average fertility of women in Britain by age and duration of marriage. No fertility figures are given for men, and so it is assumed in this estimate that they have married wives 2 years younger than themselves and the fertility of these wives estimated.

From a comparison, according to year of operation, with those traced the estimated number would be 170. The two estimates are compatible, but the first is probably the more reliable. It is, however, known (v.s.) that of

TABLE III—CHILDREN KNOWN TO BE AFFECTED AND ESTIMATED TOTAL NUMBER OF CHILDREN BORN TO 273 "UNTRACED" CASES OF PYLORIC STENOSIS CONFIRMED AT OPERATION IN 1920-29

Index case		Sons		Daughters	
Sex	No.	Known affected	Estimated total	Known affected	Estimated total
Men ..	226	3	58	0	58
Women ..	47	3	17	1	17
Total ..	273	6	75	1	75

these children at least 5 sons and at least 1 daughter (families 3, 4, 6, 8, 10 and the daughter of family 2) have had pyloric stenosis confirmed at Rammstedt's operation at The Hospital for Sick Children and 1 son had pyloric stenosis similarly confirmed at another hospital (the son in family 2). The children known to be affected and the estimated total of children born to these untraced men and women is shown in table III. The number of children known to be affected gives of course only a minimum estimate; further children may well have been affected but treated at other hospitals.

It is difficult to guess how many affected children of the "untraced" series will have been treated elsewhere; but a rough preliminary estimate, giving weight to both the "traced" and the "untraced" series and keeping the usual ratio of boys to girls affected, is that 1 son in 10 and 1 daughter in 50 have pyloric stenosis sufficient to require Rammstedt's operation. Larger and more complete series are needed to discover whether the risks of having affected children vary from family to family, whether the risks are the same for the children of male as of female survivors, whether the risk is increased after one affected child has been born, or whether one of the surviving parent's brothers or sisters was also affected.

Discussion

The proportion of sons affected is sufficiently high to make it worth watching these children in the early weeks for symptoms and signs of early pyloric stenosis. In several instances the grandmother, who was the mother of the affected parent, was sure of the diagnosis some time before the family doctor was convinced that the child had pyloric stenosis. Later when the risk is precisely known it may even be worth attempting some prophylactic treatment from birth in these families.

The aetiology of pyloric stenosis remains a mystery, but the finding that sons are unduly often affected increases the probability that genetic factors are important. It has long been known that brothers and sisters are often affected. Caulfield (1926) notes that a family with 3 affected girls was reported in the 18th century. The risk is about 1 in 10 for brothers and 1 in 50 for sisters (Cockayne and Penrose 1943, McKeown et al. 1951). This might be due to a shared environment, but it is more difficult to imagine an environmental factor which is common to two generations of a family. On the other hand McKeown et al. (1951) found no increased risk for first cousins.

It may well be that several different genes predispose to the development of pyloric stenosis, but it is worth considering the simplest unitary hypothesis that would fit the findings so far. These findings are that about 1 in 10 of brothers and 1 in 50 of sisters are affected and that the proportions of sons and daughters affected is of the same order, though less accurately known. A dominant gene producing full clinical manifestation in 1 in 5 of the boys and 1 in 25 of the girls who possess the gene would fit the findings well. The hypothesis of a recessive gene producing full clinical manifestations in 2 in 5 of the boys and 1 in 12½ of the girls who are homozygous fits the findings in brothers and sisters well. It is compatible with the findings in children, but one would expect in larger series that the proportions affected would be less and come close to 1 in 20 sons and 1 in 100 daughters. The dominant-gene hypothesis fits better at the moment, though neither explains the finding from Birmingham (McKeown et al. 1951) that there is no increased risk to first cousins. Other reasons for the dominant-gene hypothesis are that step-sibs are not uncommonly affected and that it is rare to find a relation on both the father and the mother's side of the family affected; but the strength of the arguments cannot yet be assessed statistically.

Genetic predisposition is, however, only one aspect of aetiology. Whether one assumes that a single dominant or recessive gene is mainly concerned, it is clear that only a minority of children with the gene develop symptoms of pyloric stenosis and a palpable pyloric tumour. Again the one definite conclusion from the small series of twins hitherto reported (Ford et al. 1941, Powell and Carter 1951, Metrakos 1953) is that sometimes only one

TABLE IV—BIRTH ORDER BY AGE OF ONSET OF SYMPTOMS OF PYLORIC STENOSIS, JANUARY, 1946, TO AUGUST, 1953 (Excluding 14 children whose records did not give birth order)

Birth order	Day of onset					Total
	0-6	7-13	14-20	21-27	28	
First-born ..	22	35	66	75	131	329
Later born ..	32	37	76	72	135	352
% First-born*	41	49	46	51	49	48

* First-born accounted for 46% of the 268 cases with onset at 0-20 days, and for 50% of the 413 cases with onset at 21-28 days.

of a pair of identical twins is affected, and so the penetrance of the gene or genes concerned cannot be complete. McKeown et al. (1952) have recently made two interesting observations which have some bearing on the environmental factors responsible. One is that children born in hospital develop symptoms later, on the average, than those born at home. The other is that the effect of birth order is much reduced or absent in those in whom symptoms start early. Birth order now has relatively little influence among children with pyloric stenosis confirmed at operation at The Hospital for Sick Children. The proportion of first-born is only some 5% greater than the proportion among all children

born in Greater London or London and South-East England. But an analysis of birth order by week of onset of symptoms supports the observation of McKeown and his colleagues. This analysis is shown in table IV. The proportion of all children first-born in the same area in the years 1946-51 varied from 46 to 40%. Here, as in a Liverpool sample quoted by McKeown et al. (1952), the excess of first-born becomes remarkable only when the onset is later than the third week and not, as in Birmingham, the second week. It is possible, however, that the small birth-order effect and the later onset where children are born in hospital may be due merely to more skilled baby-feeding by experienced mothers or hospital nurses.

Another line of approach to the environmental factors is suggested by the rarity of pyloric stenosis in some areas today with reasonably good medical services—for example, Malaya (Field 1951). Kellett (1933) has put forward suggestive, if not conclusive, grounds for believing that the condition was rare in Europe two or three hundred years ago. Only fifty years ago Cautley (1899) was writing that the condition was rare "though not so extremely rare as has been supposed." Now pyloric stenosis is one of the commonest disorders of childhood, with a frequency of 2-4 per 1000. It is difficult to believe that this is due merely to more complete diagnosis.

Summary

An attempt was made to trace from their original addresses 358 men and women who had pyloric stenosis confirmed at Rammstedt's operation at The Hospital for Sick Children and St. Thomas's Hospital between 1920 and 1929.

The 85 individuals traced in this way had had so far 25 sons and 21 daughters. Of these children 3 sons, but no daughters, had had pyloric stenosis confirmed at Rammstedt's operation.

The number of children born to the 273 men and women who were not traced from their original addresses is unknown but roughly estimated to be about 75 sons and 75 daughters. It is known, however, that 6 of these boys and 1 of these girls had pyloric stenosis confirmed at Rammstedt's operation because their parents (though not traced from their original address) brought them to The Hospital for Sick Children for treatment.

The children of individuals with pyloric stenosis have a risk of being affected of the same order as brothers and sisters. This strengthens the hypothesis that genetic factors are important in the causation of pyloric stenosis, though environmental factors must also play a part.

We are grateful to the members of the staff of The Hospital for Sick Children and of the Children's Department of St. Thomas's Hospital, for access to the patients under their care; and we are indebted to Dr. J. A. F. Roberts and Dr. Martin Bodian for reading this paper and making valuable suggestions.

TREATMENT OF THYROTOXICOSIS WITH POTASSIUM PERCHLORATE

M. E. MORGANS

W. R. TROTTER*

M.B. Lond., M.R.C.P.

D.M. Oxfd, M.R.C.P.

From the Medical Unit, University College Hospital Medical School, London

PERCHLORATE prevents the accumulation of inorganic iodide in the rat's thyroid (Wyngaarden et al. 1952); and in man 100 mg. of potassium perchlorate has inhibited the uptake of radio-iodine for about six hours (Stanbury and Wyngaarden 1952).

Godley and Stanbury (1954) have now used potassium perchlorate successfully in the treatment of 24 cases of thyrotoxicosis. Symptoms were relieved, and the basal metabolic rate and plasma protein-bound iodine fell to normal levels. Their observations encouraged us to undertake a clinical trial of potassium perchlorate in the hope that it might prove effective in controlling thyrotoxicosis, without exposing the patient to the risk of the toxic side-effects sometimes seen with the thiouracil drugs.

Perchlorate acts only on the iodide-concentrating mechanism of the thyroid. Thiouracil, on the other hand, leaves this mechanism unaffected but prevents the oxidation of iodide and its subsequent incorporation into protein molecules to form thyroglobulin. Thiouracil is therefore effective whatever the concentration of iodide in the blood; but perchlorate would become ineffective with blood-iodide levels sufficiently high to raise the concentration within the thyroid to the level normally attained by the gland's iodide-concentrating mechanism. In such circumstances the concentrating mechanism would become redundant and drugs which act only on it could have no effect on hormone synthesis. Hence a patient whose thyrotoxicosis is controlled by perchlorate would be liable to relapse if his blood-iodide level were suddenly raised, for example, by the administration of an iodide-containing cough medicine. This is a theoretical difficulty which might arise during perchlorate therapy, but so far we have not observed it. It might also be expected that, if a thyrotoxic patient is prepared for operation with perchlorate, similar difficulties would arise when iodide is added during the final stages to reduce the vascularity of the goitre. Godley and Stanbury (1954) found that patients prepared in this way tended to relapse in the expected manner when given iodides. For this reason we have not attempted to use perchlorate for preoperative preparation but have reserved it for patients whose thyrotoxicosis is to be treated by drugs alone.

Since perchlorate has a simple and relatively non-reactive molecule, it seemed reasonable to hope that it would not provoke hypersensitivity reactions (drug fevers, rashes, agranulocytosis, and so on), such as are observed from time to time in patients treated with any of the drugs related to thiouracil. On the other hand, it might have other unexpected properties. Godley and Stanbury (1954), treating 24 cases of thyrotoxicosis, twice observed gastro-intestinal symptoms which might have been due to the perchlorate. In one patient perforation of a duodenal ulcer was thought to have taken place; but, since the patient was treated medically, the diagnosis cannot be considered proved, and these workers were uncertain whether the event was related to perchlorate therapy or not.

The object of the present trial was to find out whether potassium perchlorate is effective, safe, and suitable for routine use in the medical treatment of thyrotoxicosis. Its effect on untreated cases has been compared with

that of methyl thiouracil and methimazole because these are the two drugs of which we have most experience. In addition potassium perchlorate has been substituted for methyl thiouracil in a group of patients already under treatment.

Methods

Potassium perchlorate was made up in tablets containing either 50 mg. or 200 mg. These were administered either once or twice daily.

The patients were usually seen at monthly intervals, when body-weight and resting pulse-rate were recorded. In previously untreated cases the plasma-cholesterol level was estimated initially and again after three or four weeks' treatment. In some cases, both untreated and those already receiving methyl thiouracil or methimazole, a white-cell count was made before starting perchlorate and repeated a month later. In some patients the efficiency of the perchlorate dosage was tested by measuring radio-iodine uptake; this was expressed either as % uptake at twenty-four hours or as the ratio of neck counts to thigh counts (neck-thigh ratio) an hour after the radio-iodine had been given.

25 patients had had no previous treatment for their thyrotoxicosis; 10 had previously completed a course of methyl thiouracil but had subsequently relapsed; 64 were receiving methyl thiouracil up to the time when perchlorate was started; and 9 were receiving methimazole. The diagnosis was based on the clinical findings but had been confirmed in all the cases either by measurement of radio-iodine uptake or by a known response to methyl thiouracil or methimazole.

Results

EFFECTIVENESS

Clinical improvement was observed in all the cases of previously untreated thyrotoxicosis. An example of the response of body-weight, pulse-rate, and plasma-cholesterol level to treatment with perchlorate is shown in fig. 1. The degree of control of the thyrotoxicosis seemed adequate in all cases but 1.

Fig. 1—Changes in plasma-cholesterol, pulse-rate, and body-weight in a patient with thyrotoxicosis before and after treatment with perchlorate. She had been under observation for loss of weight before thyrotoxicosis was diagnosed and confirmed by radio-iodine test.

After six weeks' treatment with potassium perchlorate 200 mg. twice daily this patient felt improved but not fit enough to resume work as a school-teacher. She had gained 12 lb. in weight but still had some tachycardia. Her uptake of radio-iodine in twenty-four

EFFECT OF TREATMENT FOR 3-4 WEEKS ON BODY-WEIGHT AND PLASMA-CHOLESTEROL LEVEL IN PREVIOUSLY UNTREATED PATIENTS WITH THYROTOXICOSIS

Drug	Dosage (mg. daily)	No. of cases	Body-weight (lb.)		Plasma-cholesterol level (mg. per 100 ml.)	
			Initial (mean and S.E.)	Increase (mean and S.E.)	Initial (mean and S.E.)	Increase (mean and S.E.)
Methyl thiouracil	200	25	117 ± 3.4	3.4 ± 0.9	142 ± 7.2	57 ± 6.8
Methimazole	20	14	125 ± 3.6	3.8 ± 1.1	144 ± 10.4	43 ± 8.2
Potassium perchlorate	400	16	123 ± 3.1	2.9 ± 0.9	142 ± 7.5	31 ± 7.5

The mean increase of plasma-cholesterol level is less in patients treated with potassium perchlorate than in those treated with methyl thiouracil (P 0.01). Other differences are not significant.

hours was 15% of a tracer dose. She was then changed to a combination of 200 mg. of potassium perchlorate plus 10 mg. of methyl thiouracil twice daily. After four weeks on this régime she gained a further 5 lb. in weight and resumed work without symptoms.

Although it proved possible to control thyrotoxicosis in all the other fresh cases, we gained the impression that the rate of response was less than in patients taking 200 mg. of methyl thiouracil daily. This impression is supported by the data shown in the accompanying table. The rise in plasma-cholesterol level in the patients treated with potassium perchlorate is significantly less than in those treated with methyl thiouracil.

The effect on body-weight and pulse-rate of changing from methyl thiouracil to potassium perchlorate is shown in fig. 2. A small decrease in mean body-weight and an increase in mean pulse-rate occurred in the first two months after the change-over. Both functions

Fig. 2—Changes in mean body-weight and pulse-rate in 64 patients with thyrotoxicosis who had been treated with methyl thiouracil, which was changed to what were thought to be equivalent dosages of potassium perchlorate. The limits shown are 1 standard deviation from the mean.

appeared to become stabilised after a further increase in dosage. Comparison of the dosages of the two drugs needed for control is complicated by the fact that the dosage of methyl thiouracil was decreasing at the time of the change-over. The change-over was made during the months of August, September, and October; this is a time of year when the dose necessary for control is believed to decrease (Morgans and Trotter 1949). Obviously only a crude comparison of the two drugs can be made, but it seems safe to say that the effective dosage of potassium perchlorate is from two to four times that of methyl thiouracil.

The decrease in weight and the increase in pulse-rate seen in the mean figures are mainly derived from 2 exceptional cases. One case in particular is notable in that the patient had been well controlled with moderate doses of methyl thiouracil but became severely thyrotoxic when changed to potassium perchlorate. The behaviour of her weight and pulse-rate is shown in fig. 3. It seems likely that in her case effective control will

Fig. 3—Changes in pulse-rate and body-weight in a patient with thyrotoxicosis who had relapsed after a remission following a previous course of anti-thyroid treatment. Her thyrotoxicosis was controlled with methyl thiouracil but relapsed when potassium perchlorate was substituted. Since an increasing dosage of perchlorate did not control her thyrotoxicosis, she is being treated with a small combined dosage of methyl thiouracil and potassium perchlorate.

be achieved by the combined use of small doses of the two drugs. While she was taking 400 mg. of potassium perchlorate twice daily, her uptake of radioiodine at twenty-four hours amounted to 10% of a tracer dose. In 9 other patients whose symptoms were controlled with 200 mg. twice daily, radioiodine uptakes at twenty-four hours were 10-19%; where only the neck-thigh ratios were measured at one hour the values were low normal or sub-normal. In 1 exceptional case, a man with thyrotoxicosis only partly controlled with 200 mg. of perchlorate twice daily, the uptake at twenty-four hours was 40%. His dosage has now been increased to 400 mg. twice daily; if this proves insufficient, he will be treated with a combination of perchlorate and methyl thiouracil. These are the only 2 cases in which the control of thyrotoxicosis with perchlorate has been unsatisfactory compared with the control attained with methyl thiouracil or with methimazole.

Among 108 patients treated with potassium perchlorate signs suggesting myxœdema have only once been observed; and enlargement of the goitre has been inconspicuous. These observations are compatible with the impression that perchlorate in the dosages we have used is a somewhat less potent anti-thyroid agent than methyl thiouracil.

TOXIC EFFECTS

Among 358 cases of thyrotoxicosis treated by us with methyl thiouracil toxic effects have been noted in 9% ; in two-thirds of these the methyl thiouracil had to be discontinued. The incidence of toxic effects among 23 cases treated with propyl thiouracil and 45 cases treated with methimazole was not significantly different. The reactions observed include drug fever, rashes, leucopenia, polyarthritides, and peripheral neuritis. Agranulocytosis was seen in 1 patient treated with propyl thiouracil and in 2 out of 53 cases treated with thiouracil.

None of these toxic effects has been seen among 108 cases treated with potassium perchlorate for from one to ten months. Leucopenia was not found in any of the 84 patients in whom white-cell counts were made before and after a month's treatment with perchlorate.

In view of Godley and Stanbury's (1954) experience a careful watch has been kept for indications that perchlorate might be a gastro-intestinal irritant. 2 patients have had gastric symptoms while taking perchlorate :

(1) A woman, aged 56, had had indigestion intermittently for the previous five years. This had been troublesome two years previously when thyrotoxicosis was first diagnosed. Under treatment with methimazole, and later methyl thiouracil, her gastric symptoms disappeared. They returned on changing from methyl thiouracil 50 mg. daily to potassium perchlorate 50 mg. twice daily. Epigastric pain came on half an hour after food, and there was occasional vomiting. Perchlorate was stopped after a month, and methyl thiouracil was substituted. The dyspeptic symptoms disappeared, but they reappeared when perchlorate was tried again a month later. Treatment with methyl thiouracil was therefore resumed. A barium swallow and meal showed a fair-sized sliding diaphragmatic hernia. During treatment with perchlorate there were no signs of thyrotoxicosis, and the patient's weight was steadily increasing at a slow rate.

(2) Another woman, aged 61, had had epigastric pain after meals intermittently for the previous three years. About three years previously she had had melæna. This was shortly before thyrotoxicosis had been diagnosed. The dyspepsia had not been troublesome during treatment with methyl thiouracil, but the patient had never been wholly free from it. On changing from methyl thiouracil 50 mg. daily to potassium perchlorate 50 mg. twice daily she did not notice any increase in dyspepsia. A month after the change-over she did not complain of gastric symptoms but had lost 3 lb. in weight. The dosage of potassium perchlorate was increased to 200 mg. once daily. She did not notice any increase in her dyspepsia, but a month later she was admitted to another hospital with a severe hæmatemesis. Laparotomy was done on the day of admission, but no ulcer was found. Two weeks later gastroscopy showed a small healing superficial ulcer on the lesser curve of the stomach. Two months after the hæmatemesis (no perchlorate having been taken in the interval) she was still getting some epigastric pain, with occasional vomiting. She is now being treated with methyl thiouracil, although it seems unlikely that the perchlorate was the cause of her hæmatemesis.

2 other patients who are known to have had peptic ulcers in the past had no gastric symptoms while taking perchlorate.

Discussion

Thyrotoxic patients, treated with potassium perchlorate 400 mg. daily, have on the whole responded satisfactorily. We think that the average rate of response has been somewhat slower than is usually seen after treatment with methyl thiouracil 200 mg. daily. This was only important in 1 of 25 fresh cases treated; this patient's ability to resume work was delayed, and she was therefore given a small dosage of methyl thiouracil (20 mg. daily) in addition to perchlorate. The rapid abolition of thyrotoxicosis is not always necessary or

even desirable, but in a situation where speed of recovery is important (as in thyrotoxicosis complicated by cardiac failure) it might be unwise to rely on perchlorate alone. Changing over another series of patients from methyl thiouracil to potassium perchlorate has shown that the equivalent dosage of potassium perchlorate is from two to four times as great as that of methyl thiouracil. But even on this dosage occasional patients (2 out of 64 in our series) were not so well controlled with perchlorate as they had been with methyl thiouracil. The general conclusion from our experience is that potassium perchlorate is perfectly satisfactory for controlling thyrotoxicosis in most cases, but in a few it is not completely effective. The possibility of using a combination of small dosages of perchlorate and methyl thiouracil in such cases seems worth exploring; since the two drugs act at quite different points in hormone synthesis they might well have a synergistic action.

Toxic effects from potassium perchlorate have been inconspicuous. Hypersensitivity reactions were not observed among our 108 cases, and are not to be expected on theoretical grounds. It is possible, but not yet proved, that potassium perchlorate can act as a gastric irritant in some people.

Potassium perchlorate has the advantage of being cheap. Enough tablets to treat a patient at a dosage of 400 mg. daily for a month cost 2*d.* This is from a tenth to a three-hundredth of the cost of equivalent doses of other anti-thyroid drugs in common use.

Our experience with potassium perchlorate has encouraged us to continue using it and to recommend it as worthy of further trial. The only reservations we wish to make are that it is unsuitable for use in combination with iodides for preoperative preparation; that in a few cases it has proved relatively ineffective; and that the possibility that it is a gastric irritant for some people has not yet been excluded.

Summary

Potassium perchlorate inhibits thyroid function, but its action is quite different from that of thiouracil. Perchlorate prevents the thyroid from concentrating iodide, whereas thiouracil and related substances prevent the synthesis of thyroglobulin.

When tested clinically, potassium perchlorate in a dosage of 400 mg. daily was effective in controlling thyrotoxicosis in most patients. The rate of response appeared to be somewhat slower than with methyl thiouracil, and 1 out of 25 previously untreated cases was not completely controlled.

When patients on maintenance doses of methyl thiouracil were changed over to potassium perchlorate, effective control of the thyrotoxicosis was maintained in all but 2 of 64 cases. The average dosage necessary was from two to four times as great as that of methyl thiouracil.

No toxic effects were seen in 108 patients treated with potassium perchlorate, except for possible signs of gastric irritation in 2 patients, both of whom had a previous history of dyspepsia.

We are very grateful to Dr. A. F. Godley and Dr. J. B. Stanbury for letting us see a copy of their paper in advance of publication, and to Dr. Stanbury for a very helpful discussion on perchlorate therapy. We also wish to thank Mr. W. H. Bruce, of the dispensary staff, for making the potassium perchlorate tablets, and for ascertaining the price of various anti-thyroid drugs. Messrs. Ward, Blenkinsop & Co. Ltd., supplied the methimazole.

CEREBRAL SALT WASTING

J. H. CORT

M.D. Yale

LECTURER IN PHYSIOLOGY IN THE UNIVERSITY OF
BIRMINGHAM

EXCESSIVE renal loss of sodium is usually studied with primary reference to either adrenal or pituitary insufficiency or renal disease. Welt et al. (1952) call attention to the possibility, first recognised by Claude Bernard (1858), of a more direct relationship between the central nervous system and the renal excretion of osmotically active solutes. These workers reported six cases of widely varying forms of cerebral disease (trauma, neoplasm, and infection) all of which exhibited an extreme degree of clinical dehydration, low serum-sodium levels, a negative balance of sodium of renal origin, and a lack of associated potassium retention. The patients responded only to the administration of sodium chloride, deoxycortone not reversing the renal loss of sodium; and their eosinophil-counts were distinctly lower after the administration of adrenaline. This evidence, together with their excretion of electrolytes, led Welt et al. to conclude that neither pituitary nor adrenal insufficiency played any part in the syndrome, and to postulate an interference with direct neural control of renal tubular reabsorption of sodium. In view of the work of Kaplan and Rapaport (1951) on dogs they suggested that the cause might be a failure of proximal tubular reabsorption, leading to an "osmotic" diuresis in the distal tubule. The work reported here consists of balance studies in a case resembling those reported by Welt et al.

Case-history

A housewife, aged 43, was admitted to hospital with eight weeks' history of generalised headaches and blurring of vision and three weeks' history of generalised abdominal pain and vomiting, without either comatose or ataxic episodes.

On admission the only abnormal findings were papilloedema, restlessness, and transient periods of disorientation. Soon after admission the patient experienced two grand-mal convulsions. Ventriculography revealed a mass in the region of the right posterior thalamus and hypothalamus shifting the third ventricle to the left and closing off the entrance to the aqueduct, with resulting hydrocephalus.

Progress.—The patient began to show signs of clinical dehydration, with a serum-sodium level of 128 m.eq. per litre (294 mg. per 100 ml.), and a serum-potassium level of 4.8 m.eq. per litre (18.7 mg. per 100 ml.). Simultaneously she became semicomatose, being capable of verbal response only to the simplest shouted questions, and developed ophthalmoplegia. In an attempt to correct both the dehydration and the hyponatraemia, her salt intake was gradually increased over several days, until it was about 15 g. a day, without the desired effect. By this time she was incontinent and required feeding by stomach-tube. To study her condition more fully and to determine accurate values for replacement therapy, she was put on to a constant daily intake of less than 2.5 m.eq. of sodium (with the use of 'Casilan') for two electrolyte-balance studies, one lasting three and the other nine days. Twenty-four-hour collections of urine were made under paraffin and toluene through an indwelling catheter, and she was treated with chloramphenicol to prevent urinary infection. No faeces were passed during any of the balance periods, presumably owing to the purified fluid diet.

Investigations.—Samples of blood were taken daily for the estimation of chloride, sodium, and potassium levels in the serum. The urine was examined for its specific gravity and the estimation of its content of chloride, sodium, potassium, creatinine, 17-ketosteroids, 17-hydroxysteroids, and gonadotrophin. The nine-day balance study was made as follows: first three days no treatment; fourth, fifth, and sixth days corticotrophin 30 mg. six-hourly; seventh, eighth, and ninth days deoxycortone acetate 5 mg. a day. On the tenth day she was put back on to an intake of 15 g. of sodium chloride.

Eosinophil-counts were made after the administration of intramuscular corticotrophin and after that of subcutaneous adrenaline before any hormone therapy.

Outcome.—The patient died three and a half weeks after the balance studies in gross dehydration, hypotension, and circulatory failure with terminal shock.

Necropsy Findings

The suprarenal glands weighed 24 g. and appeared normal; the pituitary gland also appeared normal. There was a small right parietal subdural abscess under the burr hole, but there were no signs of increased pressure, and the convolutions of the brain were clearly visible.

Histologically the liver showed acute fatty infiltration, with focal necrosis, predominantly centrilobular. The kidneys showed well-marked arteriosclerotic change (without evidence of arterial obstruction), congested medulla, and little vascular filling of the cortex. The pituitary stain showed patchy areas of fibrosis and scarring of the anterior lobe, but adequate normal cellular patterns; the posterior lobe was intact. The lungs showed suppurative bronchiectasis at the right base, with fibrosis and bronchopneumonia. Thigh muscle showed disuse atrophy. The suprarenal glands showed focal nodular hyperplasia, with lipid depletion in the zona fasciculata ("stress" change of Selye). In the brain, there was a pleomorphic glioma (predominantly astrocytoma) in the posterior part of the right thalamus, extending down to distort, but not directly to involve, the right posterior part of the hypothalamus. Its gross position is shown in fig. 1. A mid-brain section (fig. 2) shows an area of demyelination in the region of the right thalamo-olivary tract, involving the fibres adjacent to this tract and including the medial longitudinal fasciculus and the surrounding reticular substance carrying the descending fibres from the hypothalamus (Clark 1947). The area of demyelination ended at the rostral border of the medulla, and there were no signs of degeneration below that. No other abnormalities were found.

Results of Electrolytic-balance Studies

All the calculations are based on the chloride space assumptions set out by Gamble (1951). Table 1 shows the results of the nine-day balance study.

Cumulative balances.—On withdrawal from a sodium chloride intake of 15 g. a day, the patient was in negative balance of 100 m.eq. of Na, and 70.2 m.eq. of K for the first twenty-four hours. Thereafter she settled down to a steady loss of 60–70 m.eq. of Na and 30–50 m.eq. of K a day, and this urinary excretion was unaffected by either corticotrophin or deoxycortone. McCance's (1936) study of Na deprivation in normal man has shown that in eleven days on a Na intake of 1.5–2.5 m.eq. a day the subjects came into balance by the fifth day and were in positive balance from the sixth to the eleventh day.

Fig. 1.—Section of brain, showing tumour in right side of thalamus and encroaching on third ventricle.

Fig. 2—Section of mid-brain just anterior to the pons, showing large area of demyelination (unstained area in silver preparation) in region of right thalamo-olivary tract. Descending hypothalamic fibres are supposed to run in reticular substance just medial and superior to obvious demyelination, ventral to the aqueduct.

Serum levels.—The serum-sodium level fell from 128.3 to 108.6 m.eq. per litre and the serum-potassium level from 4.8 to 3.4 m.eq. per litre during the period of Na deprivation. Both values were restored towards normal by the administration of 15 g. of sodium chloride on the tenth day.

Extracellular fluid shifts are calculated from serum levels and chloride space and expressed as total m.eq. lost or gained from the extracellular fluid or from the chloride space. Day 1 was accompanied by the loss of 179.8 m.eq. of Na and 6.7 m.eq. of K from the chloride space. On succeeding days the rate of decrease in extracellular electrolyte fell, but the further complication developed of falling levels of these cations in the extracellular fluid.

“Intracellular fluid” shifts.—The calculated amounts of intracellular cation changed in the case of Na from a positive balance of 79 m.eq. on the first day to 15 m.eq. on the ninth day. The “intracellular” balance of K remained negative throughout at 23–63 m.eq. a day. The possible significance of these calculations is discussed below.

TABLE I—RESULTS OF ELECTROLYTE-BALANCE STUDY

E.C.F., extracellular fluid.

“I.C.F.” intracellular fluid (external balance minus E.C.F. balance).

Chloride space is calculated from serum-chloride levels and the external chloride balance expressed as an absolute volume of extracellular fluid lost or gained. The patient showed a decreasing loss of extracellular fluid from 1.4 litres on the first day to 0.90 ml. on the ninth day. After the addition of sodium chloride to the diet on the tenth day there was a calculated gain of about 1 litre of extracellular fluid.

Volume and specific gravity of urine were within normal ranges and showed no significant changes throughout the period of sodium deprivation. There was no polyuria or other evidence of faulty reabsorption of water. The urine was at all times free from protein, cells, casts, and bacteria on microscopy.

Creatinine excretion decreased progressively from 1.0 g. a day to 0.7 g. a day over the balance period and rose again to the initial value following the addition of sodium chloride to the diet.

Blood-pressure.—Both systolic and diastolic pressures showed a slight tendency to fall during the balance period but not to any significant extent.

Other urinary excretion.—The excretion of 17-keto-steroids was 8 mg. a day. The normal for a woman aged 40–50 is 4–10 mg. a day (Hamburger 1948). The excretion of 17-hydroxysteroids was 7.7 mg. a day, which is within the normal range. Gonadotrophins: equivalent as glycine, 60 mg. an hour (normal 25–200

µg. an hour); equivalent as glucose, 300 µg. an hour (within normal range).

Eosinophil-counts are shown in table II.

Discussion

The defect that has been to some degree measured in this patient involves a serious renal loss of electrolyte, particularly sodium, and a concomitant loss of extracellular fluid, the latter effect being further complicated by failure to maintain extracellular osmotic pressure. As may be expected with a loss of circulating extracellular fluid, the glomerular filtration-rate, assessed from the total excretion of creatinine, seems to have fallen by 30% during the depletion of extracellular fluid

(Cort 1952). One would expect that a falling glomerular filtration-rate would, if anything, have decreased the excretion of sodium (Warren and Stead 1944) and, far from explaining the renal loss of sodium, would tend to ameliorate this loss. The blood-pressure might be expected to fall with a decreasing volume of extracellular fluid, and indeed a slight tendency in this direction was noted. The increase in intracranial pressure, produced by the tumour, might have tended to counteract this particular change.

The absence of any signs of renal disease other than electrolyte wasting during the electrolyte-balance study before the development of terminal shock seems to indicate that the salt loss was probably due to some external influence on renal function. A lack of retention of potassium, associated with the loss of sodium and with the high normal excretions of 17-ketosteroids and 17-hydroxysteroids and gonadotrophins, would further the argument in suggesting that this extrarenal influence was not of adrenal or pituitary origin. This suggestion is further supported by the lack of response to corticotrophin and to deoxycortone.

The interpretation of the eosinophil-counts is difficult. The base-line counts were rather low, an unusual finding in pituitary or adrenal insufficiency, and there was a significant response to corticotrophin, further evidence against adrenal disease. The response to adrenaline, though a decrease, was not significant, which might suggest an interruption in some hypothalamic-anterior pituitary relationship. However, Thorn et al. (1951) cast doubt on the interpretation of eosinophil-counts by showing significant decreases in the numbers of circulating cells after the administration of adrenaline to two known Addisonian patients. Moreover, the subcutaneous administration of adrenaline involves local vasoconstriction and therefore a variable rate of absorption into the circulation from the peripheral site. If the true significance of the test could be established, perhaps it would be better to give the test dose of adrenaline intravenously, provided there were no contra-indications for such a procedure. With the exception of the adrenaline test, the entire body of data does not seem to agree with any of the known manifestations of adrenal insufficiency. Despite the areas of fibrosis in the anterior lobe of the pituitary gland there was adequate functional tissue by histological criteria.

Until recently Gamble (1951), using chloride-space assumptions, advocated equating the difference between the external and the extracellular fluid balances with the balance of intracellular fluid. If this were true, on the first day of the balance study, for example, 79 m.eq. of Na moved into cells, while only 63 m.eq. of K moved out. On the basis of the recent work by Cooke et al. (1952), suggesting that K can exchange with either Na or H at the cell membrane, the cellular exchange could be brought into balance by postulating a movement of 16 m. eq. of hydrogen ion out of cells, leaving the patient with an intracellular alkalosis and an extracellular acidosis. However, the recent demonstration that 20% of bone Na can leave bone in Na depletion (Bergstrom 1952), and the unknown quantitative nature of this exchange, make the derivation of intracellular fluid composition from balances alone very hazardous. Muscle biopsy is needed to obtain accurate data on intracellular composition of the largest cellular mass in the body.

Welt et al. (1952) suggested that the most probable explanation of the mechanism of Na loss in the kidney was decreased proximal tubular reabsorption. Since the proximal tubules usually reabsorb 85% of the electrolyte delivered to it (Walker et al. 1941), a small decrease in efficiency would present the distal tubule with a large amount of osmotic material, and might lead to an "osmotic" distal tubular diuresis. The importance of tubular locus in this discussion lies in the differentiation between hormonal and nervous mechanisms of control

of tubular function. The action of adrenal cortical steroids seems to be in the distal tubule (Smith 1951), and Kaplan and Rapaport (1947) have argued that the salt-losing syndrome produced in dehydrated dogs with denervated kidneys is due to a proximal tubular defect. No pertinent data can be presented in the present case to assist this differentiation of tubular locus. A hypertonic glucose diuresis was produced to measure the effect of such a procedure on Na excretion; but, until more data are collected from normal people and similar cases under exactly comparable conditions, little can be said of the results.

The necropsy findings in this case have been more helpful than any in the series of Welt et al. (1952), since the lesion was small enough to permit of some localisation. Both the tumour and the area of demyelination in the mid-brain were in a position to interrupt the descending fibres of both the anterior and the posterior parts of the hypothalamus. The limitation of the lesion to one side is interesting in view of Bernard's (1858) original observation that a unilateral lesion in the reticular substance at the floor of the fourth ventricle produced a diuresis of Cl without a diuresis of glucose, and that a bilateral lesion merely intensified the effect. Bernard reproduced this syndrome by renal denervation. There may be, then, a nervous connection between the hypothalamus and the proximal tubule of the kidney which influences electrolyte reabsorption. This possibility is now being actively investigated in experiments on animals.

Summary

A patient with a right posterior thalamic tumour and extreme clinical dehydration was studied by the technique of electrolyte balances, and was found to be in negative balance of both sodium and potassium. Tests of adrenal and pituitary function were normal, and the administration of corticotrophin and of deoxycortone did not affect the syndrome. The condition might be due to an interruption in hypothalamic-renal pathways affecting electrolyte reabsorption.

I wish to thank Mr. E. A. Turner, F.R.C.S., of the department of neurosurgery at the Queen Elizabeth Hospital, Birmingham, for his interest in the case, and for his permission both to study the patient and to publish the results; Dr. W. T. Smith, of the department of pathology at the hospital, for help with the histological examinations; and Miss Pamela Dawson for the biochemical determinations.

GENERAL PRACTITIONER, EWHURST

On April 4, 1953, 150 children arrived at a holiday camp at Ewhurst in Surrey. Of these children 81 were boys and 69 girls. Their ages ranged between 8 and 11 years.

The children came from three schools in the London districts of Lambeth, Dulwich, and North Kensington. On arrival none of them showed any gross skin abnormalities, but on April 7 bullous lesions were noticed on the ears of some of the boys. This outbreak was reported by the sister in charge to the visiting medical officer (E. I. B. H.).

By April 12 the outbreak had spread through the camp, and 96% of the boys and 76% of the girls were affected

DISTRIBUTION AND CLINICAL FEATURES OF JUVENILE SPRING ERYTHEMA IN CHILDREN

Lesions on hand			1	

(see table). The lesions appeared on the girls' ears about a week later than on those of the boys.

On April 14 2 of the boys were sent to St. John's Hospital for Diseases of the Skin for diagnosis, and on this occasion investigations were made to exclude any infective element. Before the investigations were completed the matter was reported to the L.C.C. medical authority, who advised that the camp should be dispersed because it was considered by them that this might be an unusual virus infection, possibly herpes simplex. The children returned to their homes on April 18. Some of the children had residual lesions on their ears; these healed, however, within a few days.

Clinical Features

The initial lesion was erythema of the helix. In a few patients this was followed by scaling only. The more characteristic clinical picture was of erythema followed within twelve to twenty-four hours by the appearance of oedematous papules or macule papules. These were deep red and in some instances showed concentric rings.

There were also smaller papules, sometimes of only pinhead size. The larger papules were sometimes surmounted by a small vesicle (fig. 1) or, less frequently, became bullous. These bullae were complicated by secondary infection, and crusting followed. As the eruption subsided, the ears showed scaling and crusting (fig. 2) but no atrophy.

In 89 of 90 patients the lesions were limited to the ears, and in most of them only the helix and lobule were involved. In some children only one ear was affected. In the more severe cases the antihelix and the tragus were involved, and in 1 patient there were lesions on the back of the hands and the dorsa of the fingers (fig. 3). The appearance of lesions on the hands, and the fingers were those of erythema multiforme; and indeed the aural lesions described above may also be considered as a localised form of this disease.

In addition to the skin lesions some of the children had enlarged cervical glands, the greater glandular enlargement being found in those children who had bullous lesions on the ears. At first it was thought that the glandular enlargement was associated with throat infection, because several of the children had enlarged tonsils or inflammation of the fauces; but this was later found to be coincidental.

Fig. 1—Papular and maculopapular lesions on ear, showing early vesiculation.

Investigations

Virus studies were made on vesicle fluid obtained from the patients seen at St. John's Hospital for Diseases of the Skin, and the cytology of the base of the vesicle was examined.

Cytology revealed no evidence of virus infection. There was no evidence of herpes simplex virus in animals inoculated with vesicle fluid.

Historical

The older literature concerning this dermatosis is rather confused, and it seems that little distinction was made between herpes simplex activated by sunlight and this eruption, both of them being described under the heading of *l'herpès des Alpinistes*. Koehler (1938) suggested that the disease was first described by Von Gaal (1858), who described an epidemic in a group of prisoners in Bosnia.

Thibierge and Rabut (1921) described a dermatosis similar to our juvenile spring erythema under the name *une éruption papuleuse et prurigineuse développant*

Fig. 2—Bullous lesions on ear, showing crusting.

Fig. 3—Lesions resembling erythema multiforme on hand.

au printemps sur les mains des jeunes sujets. Although in 9 patients the lesions were limited to the backs of the hands and fingers, in 2 of them lesions appeared on the face as well. The patients were aged 5½–12 years, and the eruption lasted from eight days to three weeks. Various plants were suspected as actinological agents causing photosensitivity. These workers mention that in thirty years they had seen one or two instances of this disorder yearly in April and May. It was apparently then known as *prurit vernal des jeunes sujets*.

Jausion and Pagés (1933) mention a somewhat similar disorder in 9 soldiers engaged in gardening. This disease was named *photodermite dysidrosiforme des acrocyanotiques*.

Koehler (1938) described an outbreak of this dermatosis as an epidemic of erythema exudativum multiforme. He observed 186 men from a German labour camp, some of whom had lesions on the ears and on the backs of the hands. The photographs accompanying Koehler's paper are very like ours. The epidemic was extensively investigated, and a record of meteorological findings in the camp is given for the time of the onset of the epidemic:

Meteorological Findings (evening forecast at 9.25 P.M.).—Wind strength zero. Humidity: rel. 82%, absolute 3.9. Air-temperature 0.3°C. Ground-temperature at 10 cm. depth 6.8°C, at 20 cm. depth 7.5°C.

General Weather Forecast.—Variable cloud and snow several times during the day on higher ground, clear in the evening.

Koehler thought cold was an important factor and did not discuss the influence of sunlight.

Keining (1940) described the same condition under the name "spring perniois." He believed that its peculiar distribution was to be explained by the fact that the ears and hands are perniotic areas. In particular he describes "capillary stasis" in these areas. Koehler (1938) mentioned that Kaposi (1900) believed that the distribution

of erythema multiforme was according to where capillary stasis developed.

Burckhardt (1942) described the condition as an actinic dermatosis affecting the ears during the spring. In the spring of 1941 and 1942, during a spell of unusually fine weather, he observed the dermatosis among high-school children in Zürich. In a class of 50 boys 44 had papules and crusts and 1 had crusting only of the ears. Among 50 girls, most of whom had their hair over their ears, only 1 had crusts on the ears. A biopsy specimen from 1 patient showed the histological picture of erythema multiforme. Burckhardt believed that the eruption was an actinic reaction, but he could not reproduce the lesions with a Kromayer lamp. Therapeutically he had the impression that nicotinamide produced some relief of the disorder. The idea of using nicotinamide probably derived from the report of Keining and Oldach (1941), who used nicotinamide in the treatment of erythema multiforme.

Discussion

The ætiology of this disorder is still unsettled. The published reports and our own observations seem to show that it is predominantly an actinic reaction.

Among our patients there were more boys than girls, and the boys had a more severe form of the eruption. This is probably because the girls' hair covered their ears, protecting these somewhat from the sunlight.

In this outbreak, as in others, the children had come from city homes, where exposure to direct sunlight was less common than in the country, where they were playing out of doors most of the day.

We were unable to support the idea that the so-called epidemic was due to an infection. In most years sporadic cases of this dermatosis are seen by dermatologists and general practitioners, and the large numbers of cases recorded from this camp were probably due to the fact that all these children were exposed to particular climatic conditions.

Climatic data obtained from the Air Ministry meteorological office for April 4–18, 1953, taken at two stations about twelve miles from the Ewhurst camp, indicate that this was a particularly fine period. On seven of the fourteen days the number of hours of sunshine daily was more than 6.0, and on April 7, when the eruption was first noticed, there were 9.1 hours of sunshine. The wind was mild to moderate on most days. It was rather cold.

From these figures and those of Keining (1940) it is suggested that the combination of sunlight and cold is important.

Hitherto we have been unable to determine whether any particular wave-lengths of light are responsible; nor have we attempted to reproduce the eruption artificially.

Summary

An unusual outbreak of dermatosis mainly affecting the ears occurred in April, 1953, among London school-children sent to a holiday camp in Surrey.

The eruption is thought to have been an actinic reaction precipitated by exposure to sunlight and cold.

We are indebted to Dr. J. A. Dudgeon for the virus investigations.

WHITE NAILS IN HEPATIC CIRRHOSIS

RICHARD TERRY

M.D. Lond., M.R.C.P.

CONSULTANT PHYSICIAN, DREADNOUGHT SEAMEN'S HOSPITAL, GREENWICH; SENIOR REGISTRAR, ST. BARTHOLOMEW'S HOSPITAL, LONDON

PALLOR of the finger-nails is commonly seen in anæmia and with vasoconstriction of the nail bed. The nails themselves become whitened and opaque in leuconychia totalis, which, according to Pardo-Costello (1936), is extremely rare: although it is not associated with any particular disorder, he has seen it in leprosy, trophic disturbances of the extremities, and chronic arsenical poisoning. Other references to leuconychia are similar and also indicate that the opacity is in the nail rather than the nail bed (Howard et al. 1917, Weiss 1918, Pernet 1919, Studenbord and Studenbord 1935, O'Donovan 1938). The present report is concerned with opacity of the nail bed causing *apparent* whiteness of the finger-nails, and its occurrence in cirrhosis of the liver and some other conditions.

Appearance of White Nails

Fully developed white nails exhibit a ground-glass-like opacity of almost the entire nail bed. It extends from the base of the nail, where the lunula is indistinguishable, to within one or two millimetres of the distal border of the nail bed, leaving a distal zone of normal pink. The condition is bilaterally symmetrical, with a tendency to be more marked in the thumb and forefinger. In less "classical" examples the opacity varies widely in degree and distribution (see accompanying figure).

Demonstration of Opacity

Any vasoconstriction of the nail bed is overcome by grasping the penultimate phalanx of the patient's finger or thumb and squeezing blood into the terminal phalanx, while the patient flexes the terminal joint. The normal nail bed becomes congested and, except for the lunula, attains a uniform pink colour varying in intensity with the level of hæmoglobin. Any whiteness of the nail bed is unaffected by the congestion and indeed is accentuated by contrast with the congested distal pink zone.

Characteristics of White Nails in Cirrhosis

Prevalence.—White nails were found in 82 of 100 consecutive patients with cirrhosis. The aetiology of the

cirrhosis was alcoholic in 91, postnecrotic in 7, and cholangiolitic in 2. The 18 patients without white nails were all among the alcoholic group.

Nails Affected.—In nearly all the cases where white nails were present all the nails in both hands were affected.

Density of Opacity.—The opacity or whiteness of the nails was graded as gross in 6 patients, severe in 23, moderate in 42, and slight in 11. (In this grading gross=lunula indistinguishable, severe=lunula just visible, moderate=lunula easily visible, and slight=opacity just apparent.)

Gradation of Opacity in Same Hand.—All the nails were equally white in 29 patients, but in the remainder there was usually some gradation. Thus the opacity decreased regularly from the thumb to the little finger in 34 and increased regularly in 6. Regular gradations from other fingers were present in 10, and there was complete irregularity in only 3 patients. Whatever the gradation, it was always the same in both hands.

Distal Pink Zone.—The white opacity covered the whole nail bed of all the fingers in some cases, but more usually it stopped short of the finger-tip in one or more nails, leaving a distal pink zone of normal nail bed.

Irregularity of Distal Pink Zone.—The distal border of the opacity was usually well defined and ran across the nail parallel to the end of the nail bed, leaving a regular distal pink zone. In 29 instances, however, the border was uneven in some of the nails, producing an irregular distal pink zone.

Symmetry.—The density of the opacity was often strikingly similar in corresponding fingers in the two hands, and was identical in all five corresponding fingers in 24 patients. Whether the opacity extended to the end of the nail bed or stopped short of it, the corresponding fingers in each hand were usually affected alike. Symmetrical distribution of the opacity was present in all five fingers in 47 patients. Irregular pink zones were present in corresponding fingers in 16 patients. In many instances the irregular distal borders of the opacity in corresponding nails were mirror images of one another.

Other Changes.—Severe longitudinal ridging of the nails was common, as was some thickening. Flattening of the nails, however, was only seen in 2 instances, in contrast to the experience of Kleeberg (1951), who reported its frequent occurrence in cirrhosis.

Correlation.—Of patients with spider naevi 37% had severe or gross white nails, compared with 22% of those without naevi. Otherwise no correlation was found with any clinical or laboratory findings.

Further details are shown in the accompanying table.

NUMBER OF NAILS IN EACH HAND EXHIBITING VARIOUS FEATURES OF WHITE NAILS, AS SEEN IN 100 PATIENTS WITH CIRRHOSIS

Character	Number of nails affected in each hand					
	5	4	3	2	1	0
White nails	73	6	1	1	1	18
Distal pink zone .. .	21	14	9	9	12	17
Irregular pink zone ..	0	3	4	9	13	36
Symmetry of density ..	24	23	16	14	3	2
Symmetry of distribution ..	47	16	11	6	2	0

CASE-REPORTS

The following are five typical examples of well-developed white nails in various forms of cirrhosis:

Case 1.—White male aged 44. Chronic diarrhoea for twelve years, aetiology unknown. Huge nodular liver and splenomegaly. Liver biopsy revealed postnecrotic cirrhosis. All the nails exhibited gross opacity with distal pink zones (see figure).

Finger-nails of case 1 showing well-developed white nails and distal pink zones.

Case 2.—White male aged 72. Postnecrotic cirrhosis with symptoms of hepatic insufficiency for three years. Thumbs showed gross opacity, forefingers severe, middle fingers moderate, and ring fingers slight opacity, while the little fingers were normal. Distal pink zones were present in all the white nails.

Case 3.—Coloured girl aged 16. Hepatosplenomegaly since infective hepatitis at age of 9 years. Postnecrotic cirrhosis following viral hepatitis diagnosed. Chronic ascites present, but no stigmata of cirrhosis. Gross opacity of thumb-nails and severe opacity of other nails. Distal pink zones well marked.

Case 4.—White woman aged 39. Homologous-serum jaundice following multiple blood-transfusions for hæmorrhage from placenta prævia at age of 36. Jaundice never cleared completely; gradual downhill course with development of hepatosplenomegaly, persistent ascites, hæmatemesis, and anæmia. Gross white opacity of all nails, with ivory-like opacity of nails of thumbs and forefingers. Necropsy revealed cholangiolitic cirrhosis.

Case 5.—White man aged 38. Laennec's cirrhosis associated with twenty years' alcoholism. Opacity slight in thumbs, moderate in forefingers, and severe in the rest.

White Nails in Other Conditions

PHYSIOLOGICAL

Many young children aged 1–4 years exhibit various degrees of "classical" white nails, while in perfectly good health and in the absence of any suggestion of hepatic disorder. In all the examples observed in young children the opacity was equal in all the nails, there were a regular distal border and a pink zone, and the intensity was never more than moderate to severe.

Case 6.—Boy aged 2½ years. History and examination were normal apart from one small spider nœvus on the hand and well-developed palmar erythema. All the finger-nails showed severe white opacity with narrow distal pink zones of unknown duration. At the age of 3 years the distal pink zones had widened and the opacity was less severe. At the age of 3½ years the opacity had further diminished and was almost graded as slight. In view of this first observation in a child the next case was watched from an earlier age.

Case 7.—A healthy male child, aged 9 months, was found to have no white opacity of the nails apart from the lunula. The nails remained clear until the age of 15 months, when the first suggestion of opaque nail beds appeared, and at the age of 16 months the opacity had become severe.

In normal young women up to the age of 20 some opacity of the nail bed is quite common and occasionally severe.

OTHER DISORDERS

All degrees of whiteness of the nails have been seen in a variety of other disorders, including chronic congestive heart-failure, diabetes (especially in young patients), pulmonary tuberculosis, rheumatoid arthritis, convalescence from viral hepatitis (especially in adolescents), disseminated sclerosis, and some forms of carcinoma. These observations are at present random and few, and a more detailed investigation is being made.

Nature of White Nails

In leuconychia striata and punctata the white areas are in the nail itself, and, as the nail grows, they steadily move towards the finger-tip and are finally eliminated when the nail is cut. Leuconychia totalis is apparently a more diffuse example of the same disorder. These opacities are attributed variously to air-bubbles within the nail, to incomplete keratinisation, or to the persistence of nucleated cells in the nail.

The white opacity described here is entirely different. Neither the white opacity nor the distal pink zone alters as the nail grows. The nail itself is normally transparent, and the opacity evidently results from some change in the nail bed.

The nature of this change in the nail bed is less certain. The lunula is apparently produced by the proximal

portion of the matrix. According to Burrows (1919) the matrix is not so firmly adherent to the underlying vascular connective tissue in the region of the lunula as it is elsewhere, and this separation produces a reflecting surface with apparent opacity. It seems most probable that the opacity of white nails is in the superficial layers of the matrix and is of similar nature to the opacity of the lunula.

Ætiology and Significance of White Nails

The manifestations of cirrhosis include gynæcomastia, spider nœvi, cutaneous striae, and palmar erythema. Some or all of these conditions are also seen in children, adolescents, pregnancy, pulmonary tuberculosis, rheumatoid arthritis, congestive heart-failure, and some forms of cancer. If it is accepted that these are manifestations of abnormal steroid metabolism, as many deem likely, then it is conceivable that white nails, which occur in the same range of disorders, may have the same origin.

It has not been possible to relate the presence or absence of white nails or their degree to any of the clinical or other features of cirrhosis of the liver. This lack of correlation is also a feature of the accepted endocrine stigmata of cirrhosis, particularly spider nœvi (Bean 1945). It may well be that each separate endocrine stigma reflects the faulty metabolism of a particular adrenal steroid, and that a specific steroid is responsible for the white nails of cirrhosis and other disorders.

Discussion

White opacity of the nail bed giving rise to apparent whiteness of the nails is relatively common and has been observed by me on many occasions in addition to the 82 instances reviewed here. In nearly all these cases the condition of the nails had been entirely overlooked; and in the few where the whiteness had been noted it had been dismissed as due to either anæmia or vasoconstriction. These appear to be the chief reasons for the neglect of white nails as a physical sign.

These nails are common in cirrhosis of the liver and may fairly be added to the list of non-specific physical signs thereof. Their diagnostic value in cirrhosis is limited, since they occur in other conditions, but they are occasionally most helpful in suggesting or corroborating the diagnosis. These remarks are particularly applicable to coloured patients, in whom such signs as palmar erythema and spider nœvi are rare or difficult to see.

Apart from young children and adolescents, well-developed white nails have not been seen in healthy people. Their presence is therefore at least a suggestion of ill health, present or impending, and a stimulus for further investigation and observation.

Summary

Opacity of the nail bed with *apparent* blanching of the nail is common. It was found in 82 out of 100 consecutive patients with cirrhosis hepatitis, and occasionally in certain other conditions.

White nails are easily overlooked; their demonstration and appearance are described.

It is suggested that white nails are endocrine stigmata, comparable with spider nœvi, palmar erythema, cutaneous striae, and gynæcomastia.

Well-developed white nails are apparently rare in healthy adults, and their detection may therefore be of some importance.

I wish to thank Dr. R. Bodley Scott for permission to refer to the patient in whom the initial observation of white nails in cirrhosis was made and whose nails appear in the accompanying figure. Nearly all the above observations were, however, made during the tenure of a research fellowship at the Hektoen Institute for Medical Research of the Cook County Hospital, Chicago, granted by the Jerome K. Solomon Memorial Foundation. I am particularly grateful to Dr. Hans Popper and to Dr. Frederick Steigmann, of the Hektoen

Institute, for their advice and encouragement. I am indebted to the photographic department of St. Bartholomew's Hospital for the illustration.

**PSEUDOMONAS PYOCYANEA MENINGITIS
 SUCCESSFULLY TREATED WITH
 POLYMYXIN**

DAVID H. TRAPNELL
 M.A., M.B. Camb.

SENIOR HOUSE-OFFICER, GUY'S-MAUDSLEY NEUROLOGICAL
 UNIT, MAUDSLEY HOSPITAL, LONDON

SINCE the advent of the polymyxins as therapeutic agents in 1949 little has been published on their use in meningitis caused by *Pseudomonas pyocyanea* (*aerogenes*). Seven cases of meningitis due to this organism treated with one of the polymyxins (of which B and E are the least toxic) have been recorded in the United States (Schoenbach 1949, three cases; Hayes and Yow 1950, Tomlin 1951, Kagan 1952, and Jawetz 1952, one case each). So far as I can discover, no case of *Ps. pyocyanea* meningitis treated with polymyxin has been published in this country. The following case is therefore presented.

Case-record

A boy, aged 5½ years, was admitted to hospital for re-exploration of a cervical-cord ependymoblastoma after a course of deep X-ray therapy. Eight days after operation (Mr. Murray Falconer) he developed a small cerebrospinal-fluid (c.s.f.) fistula at the upper end of the incision, which closed within two days. Two days later (Aug. 24, 1953) he developed meningitis (500-3000 white cells per c.mm.).

Treatment with procaine penicillin 300,000 units b.d. and intramuscular streptomycin 0.5 g. b.d. for four days, followed by oral oxytetracycline 250 mg. eight-hourly for four days, and then with chloramphenicol 500 mg. six-hourly by mouth and 3 g. intrathecally daily for twenty-three days did not produce any sustained clinical improvement.

Culture of c.s.f. on various occasions gave a pure growth of *Ps. pyocyanea*, the sensitivities of which to various antibiotics were as follows:

Antibiotic	Organism sensitive	In-vitro concentration
Sulphadiazine	-	10 mg. per ml.
Penicillin	-	100 units per ml.
Streptomycin	-	100 µg. per ml.
Aureomycin	+	100 µg. per ml.
Chloramphenicol	+	50 µg. per ml.
Oxytetracycline	+	50 µg. per ml.
Polymyxin	+	6 units per ml.

Bacteriological Techniques.—The causal organism was isolated from the c.s.f. by inoculating the centrifuged deposit into 50 ml. of glucose broth. During the course of treatment this had the effect of diluting any residual polymyxin, but often growth was not apparent until after forty-eight hours' incubation. Attempts to recover the organism by plating the deposit on solid media failed repeatedly. Initial sensitivity tests were made by the plate method using antibiotic tablets (Evans Medical Supplies Ltd.). Tube sensitivities were determined with doubling dilutions of the various antibiotics in nutrient broth. One drop of a 1:300 dilution of an eighteen-hour broth culture was used as the standard inoculum. Results were read after eighteen hours' incubation at 37°C. The sensitivity of the organism to polymyxin was tested again during treatment, and there was no evidence of increased resistance to the antibiotic. Polymyxin levels in the c.s.f. were estimated by the tube method with doubling dilutions of c.s.f. in nutrient broth. The racks were inoculated with a broth culture of *Escherichia coli* (N.C.T.C. 6064), which was sensitive to 0.3 units of polymyxin per ml.

First Course of Polymyxin.—Since the organism was sensitive to therapeutic concentrations of polymyxin alone, treatment with this antibiotic was begun on Sept. 25, 200,000 units being given intramuscularly four-hourly and 40,000 units intrathecally twelve-hourly for three doses and thereafter once daily. Twenty-four hours later the boy's temperature was normal for a few hours, and by the third day it remained normal all day. Simultaneously there was an improvement in the c.s.f., the white-cell count falling to 110 per c.mm. on the sixth day (Oct. 1). Cultures were sterile on the fourth and fifth days of treatment, the blood-polymyxin level twenty-four hours after the preceding intrathecal injection being 19 units per ml. on the sixth day. Treatment was stopped on the eighth day because of these favourable results and because toxic effects had appeared.

Toxic effects were first noticed shortly after the treatment started, when the boy's appetite became very poor and he began to vomit after each meal. He was given an entirely fluid diet (milk and fruit juices with added salt and sugar), but even so vomiting was frequent and, had it continued for long, would certainly have weakened his resistance to the infection and caused serious metabolic imbalance. After two days sacral oedema appeared, and on the third day he had mild oedema of the face, but these features disappeared after forty-eight hours, even though treatment was being continued. A mid-stream specimen of urine at this stage showed no casts and only a trace of protein. The sites of intramuscular injections (buttocks and thighs) showed localised induration and tenderness but no superficial erythema, the injections themselves being painful, even when given slowly. After each intrathecal injection the boy would cry with pain down both legs for about an hour. This was assumed to be due to the irritant effect of polymyxin on the cauda equina. Thorough mixing of the polymyxin solution with c.s.f. before injection made the pain less severe but did not eliminate it. All these side-effects of polymyxin disappeared within forty-eight hours of cessation of treatment. Coincidentally there was a general improvement in his condition and appetite.

Second Course of Polymyxin.—Three days later (Oct. 5) a lumbar puncture, done as a check on his progress, showed a white-cell count of 7640 per c.mm., and a pure growth of *Ps. pyocyanea* was obtained after forty-eight hours' culture. It was assumed that a localised collection of pus, which had not been sterilised by the first course of treatment, had burst

Pseudomonas pyocyanea meningitis treated with polymyxin B

into the c.s.f. The boy's general condition grew rapidly worse, his temperature rising to 103.6°F. Polymyxin-B therapy was therefore restarted (Oct. 6), 200,000 units being given intramuscularly four-hourly and 40,000 units intrathecally daily. Within thirty-six hours his temperature again became normal for a few hours, but did not remain so until Oct. 11. Next day (Oct. 12) the systemic dose was decreased to 200,000 units eight-hourly and further decreased to 200,000 units twelve-hourly (Oct. 15) for the next fourteen days. Apart from four days (Oct. 13-17) during which the daily intrathecal dose was halved, 40,000 units was given daily until the thirty-seventh day (Nov. 3), 20,000 units being given for two further days.

Cultures of c.s.f. showed a pure growth of *Ps. pyocyanea* until Oct. 21, after fifteen days of the second course of treatment. Then the culture was sterile after prolonged incubation (the c.s.f.-polymyxin level twenty-four hours after previous injection was 20 units per ml.), and thereafter it remained so. The c.s.f. white-cell counts ranged between 100 and 500 per c.mm., and the pleocytosis disappeared within two weeks of the end of intrathecal treatment (see figure).

Toxic Effects.—During this second course eosinophilia, xanthochromia of the c.s.f., and a transient mild albuminuria with granular and hyaline casts appeared, the blood-urea level remaining normal. A white-cell count on Oct. 13 (seventh day of second course of treatment) showed a total count of 13,100 per c.mm. (neutrophil polymorphs 84%, eosinophils 3%, lymphocytes 12%, monocytes 1%). The Hb was 9.1 g. per 100 ml., and the red cells showed considerable microcytosis and hypochromia and some anisocytosis. A transfusion of 1 pint of whole blood was given on Oct. 16. Three days later (Oct. 19) a blood-count showed 19,900 white cells per c.mm. (eosinophils 18%, neutrophils 67%), and Hb 12.5 g. per 100 ml. A later blood-count (Oct. 26) showed 18,100 white cells per c.mm. (eosinophils 32%, neutrophils 56%, lymphocytes 11%, monocytes 1%) and Hb 11.9 g. per 100 ml. There was no allergic reaction at any stage, nor was there any past history of allergy. The eosinophilia became even more pronounced and on Oct. 30 was 41% of a total of white-cell count of 14,800 per c.mm. (neutrophils 46%, lymphocytes 13%), with Hb 11.7 g. per 100 ml. A radiograph of the chest at this stage was normal. Eosinophils appeared in the c.s.f. at the same time as in the blood and in about the same percentage of the polymorph-count. Xanthochromia of the c.s.f. became marked soon after the beginning of this course, but while the intrathecal dose was decreased (Oct. 13-17) it was much less so, increasing again with the higher dosage. It disappeared within two days of the end of intrathecal treatment.

Further Progress.—Clinically the boy's improvement was steady and rapid, and a week after the end of treatment he was kicking a football about the ward. Six months after the end of treatment he continues to progress and has shown no evidence of relapse.

Discussion

Pseudomonas meningitis is rare. Stanley (1947) could find records of only forty-one cases of primary infection and twenty-nine (including one of his own) in which the meningitis was secondary to a focus elsewhere. Since then at least eighteen others have been described. The condition will probably become more common as a result of the more widespread use of antibiotics which are effective against most organisms but not against *pseudomonas*. The mortality in this condition is high. Stanley (1947) found a mortality of 55% in cases due to primary infection and "at least" 86% in secondary cases. If and when it occurs, therefore, it is clearly most important to be able to combat this infection with some safe and powerful agent. Polymyxin B and possibly neomycin (Ditkowsky et al. 1952, Knight et al. 1952) appear to meet this need.

The course of treatment in the present case was much longer than others recorded (except the case of Hayes and Yow 1950, where three courses of treatment were given because of relapse), and, perhaps as a result of this, toxic effects not previously described appeared. The second course of treatment was continued for thirteen days after the cultures became sterile, to avoid another relapse.

It was during the second phase that the new toxic features appeared—considerable eosinophilia (up to 41%) and xanthochromia of the c.s.f. The eosinophilia in the blood, which was also reflected in the polymorph response in the c.s.f., presumably must be due to the polymyxin therapy, there being no evidence of other allergic phenomena or radiographic evidence of any lung changes. The eosinophil-count returned to 6% within thirteen days of the end of the polymyxin therapy. The xanthochromia, like the pain down the legs, was presumably the result of a chemical irritant effect of the polymyxin, for it seemed unrelated to the number of red cells in the c.s.f. It did not appear until early in the second course and was much less severe while the intrathecal dosage was reduced, returning when the dosage was increased to its former level. After the intrathecal polymyxin was discontinued, the xanthochromia disappeared completely within two days. Trauma due to repeated lumbar puncture was not the cause, for the patient had had frequent lumbar punctures during the month before the polymyxin therapy and for several weeks afterwards without xanthochromia appearing.

Signs of renal damage were never severe; even when the urine changes were maximal, the blood-urea level was normal. This is in accordance with the findings of Swift and Bushby (1953). Polymyxins B and E do not usually cause renal damage, but if signs of renal damage appear they soon disappear when treatment is withdrawn. The polymyxin B used in the present case caused no pyrexia, as has been recorded by other workers, and no perianal or perioral anaesthesia as in Tomlin's (1951) case. Pain in the back and down the legs following intrathecal polymyxin injections occurred in the cases of Hayes and Yow (1950) and Tomlin (1951) and in this patient, but ceased after about two weeks' treatment in spite of continued full intrathecal dosage. Similarly the malaise and vomiting, which also were recorded by Hayes and Yow (1950) and Swift and Bushby (1953), disappeared in spite of continued intrathecal and intramuscular treatment. The mild pleocytosis in the c.s.f. which remained at the end of the treatment was probably the direct result of it, for within two weeks of its conclusion the cell-count had fallen to normal levels. This effect was also noted by Swift and Bushby (1951) using intrathecal polymyxin E.

Such was the virulence of the infecting organism, and its resistance to other antibiotics, that this case probably would have proved fatal but for polymyxin therapy. This drug is the one of choice for *pseudomonas meningitis* in spite of its toxic effects, which were not great in the present case, even with long-continued high dosage. Prompt polymyxin therapy in adequate dosage (intramuscular and intrathecal) and continued for at least ten days after the c.s.f. is sterile seems to give a patient with this grave disease his best chance of permanent recovery.

Summary

A case of *Pseudomonas pyocyanea meningitis* following a cerebrospinal-fluid fistula is described. The causal organism was resistant to sulphonamides, penicillin, aureomycin, oxytetracycline, and chloramphenicol, but sensitive to polymyxin B. Recovery followed a long course of intrathecal and intramuscular polymyxin B.

Previously unrecorded toxic effects of polymyxin therapy—severe eosinophilia and xanthochromia of the c.s.f.—are described. Other toxic effects observed were nausea and malaise, pain at the injection site, pain down the legs and in the back following intrathecal injections, and sacral oedema. These effects disappeared in spite of continued polymyxin therapy. Transient mild albuminuria with cylindruria was also present.

I am most grateful to Mr. Murray A. Falconer for permission to publish this case; Dr. K. Anderson, of the bacterio-

logy department, Guy's Hospital, for estimations of the sensitivities and blood-polymyxin levels and the note on the techniques used; and Dr. D. R. C. Wilcox, clinical pathologist, Maudsley Hospital, and his staff for daily examination of the c.s.f. for more than two months.

TRICHOBEZOAR

H. S. TRAFFORD

M.B. Manc., F.R.C.S.E., D.Obst.

SENIOR SURGICAL REGISTRAR, BIRMINGHAM GENERAL HOSPITAL

BEZOARS are masses of foreign material sometimes found in the stomach and intestines of man and animals. Phytobezoars are masses of unabsorbed fruit and vegetable residue, and trichobezoars are masses of hair. The latter usually accumulate in the stomach for years when persons or animals eat their own hair.

Published reports of hair-balls in man are comparatively few. The first report was that of Baudamant (1779) and the first report of successful surgical removal of a trichobezoar was made by Steltzner (1896). DeBailey and Ochsner (1938) reviewed 172 cases of hair-balls, of which 15 were associated with peptic ulceration and 5 were complicated by perforation. 13 further cases were published up to 1948, including 1 by Parsons (1948) in which the mass was palpable in the abdomen. Nussey and Leask (1949) reported a hair-ball in a woman, aged 40, that completely filled the stomach and formed a cast. Osmond and Price (1951) reported what was thought to be the first successful operation for repair of a perforated gastric ulcer due to a hair-ball in a girl aged 8 years.

Trichobezoars are usually large and solitary but occasionally multiple. The largest on record seems to be that removed by Davies (1921); this weighed 6½ lb. when fresh. DeBailey and Ochsner (1938), however, reviewing the 172 cases then reported, considered that their own example, which weighed 1.6 lb., was of about average size.

It is thought that the stomach cannot expel hair and allied material when ingested, and that ultimately a bolus of ever-increasing size is formed in the stomach. More than 80% of trichobezoars occur in people aged less than 30, and more than 90% in females. The predominance in females is thought to be due to their longer hair, which is more easily pulled out and chewed. In a fairly large proportion of cases there is evidence of mental instability.

While the hair-ball remains small, no symptoms need be associated with it. Later the patient may complain of anorexia, general malaise, loss of weight, or even of a feeling of epigastric fullness or a palpable mass in the abdomen. If the hair-ball is near the pylorus, a condition resembling pyloric stenosis may result, with paroxysmal vomiting and epigastric pain. Ulceration, perforation, and peritonitis may ultimately supervene. The treatment is surgical removal as soon as bezoar is diagnosed. Postoperatively adequate precautions, both physical and directed at the mental state, must be taken to prevent further ingestion of hair.

The following personal case seems well worth reporting because the trichobezoar was found in the terminal

ileum and had given rise to intestinal obstruction. I have not been able to find any similar published case.

Case-report

A girl, aged 7 years, was admitted to the North Staffordshire Royal Infirmary in 1949 with twenty-four hours' history of colicky abdominal pain and vomiting. There was no previous history of any abdominal symptoms whatever.

On examination the general condition was good, but the lower abdomen was distended and showed an early ladder pattern suggesting small-bowel obstruction. A firm sausage-shaped mass was clearly felt in the right iliac fossa. Ileocaecal intussusception was provisionally diagnosed, and the abdomen was opened by a right paramedian incision under general anaesthesia. The mass proved to be a foreign body in the terminal ileum 6 inches from the ileocaecal valve. It was removed through a small incision in the long axis of the bowel, which was sutured transversely to prevent a stricture from forming. The foreign body was a hair ball. The stomach was palpated, but no further masses were felt. The child made an uninterrupted recovery and was discharged on the twelfth postoperative day. She has remained well since.

A history was later obtained from the parents that the child had been noticed to chew her hair from early childhood.

The specimen was 4 inches long and 1½ inches in diameter and resembled a thick sausage. It consisted of innumerable black hairs packed together almost inseparably and weighed 12 oz.

Summary

A trichobezoar left the stomach of a girl, aged 7 years, and became impacted in the ileum, causing obstruction which closely resembled intussusception.

My thanks are due to Mr. L. M. Zinck, F.R.C.S.E., for permission to publish this case-report.

Reviews of Books

The Physician in Atomic Defence

THAD P. SEARS, M.D., F.A.C.P., associate clinical professor of medicine, University of Colorado School of Medicine. Chicago: Year Book Publishers. London: Interscience Publishers. 1953. Pp. 308. 45s.

THIS book deals with the fundamentals of nuclear physics, the injuries caused by atomic bombs, and the administrative plans to meet such disasters in the United States of America. For those unable to attend courses or lectures on these subjects, it sets out the sort of indoctrination they would receive.

Professor Sears is most at ease when he is presenting simplified concepts of modern physics in a readable form. He is not so strong in outlining the rôle of the physician tending atomic bomb casualties: the management of all forms of injury is summarised inadequately in a few pages, and his account hardly presents in realistic perspective the problem likely to be encountered. The casualty figures estimated for airburst explosions make sombre reading; they apply, it seems, to attacks against unwarned communities, or with very powerful weapons. In either event, blast and burning injuries—about which he says little—would outweigh radiation effects among survivors. On the other hand, the medical aspects of an underwater explosion (when radiation effects would outnumber blast and burning injuries) are not discussed.

Traité de cytologie sanguine

MARCEL BESSIS. Paris: Masson. 1954. Pp. 588. Fr. 6800.

A VOLUME with this title leads one to expect a detailed account of the morphology of normal and pathological blood-cells with illustrations of their appearances as seen under the microscope; for most books of this type are designed for clinical pathologists and stick to classical

methods of preparation and recognition of blood-cells. Dr. Bessis's book differs from these in adding to classical methods results obtained with other techniques now coming into use. These are cytochemical techniques for showing up particular cell constituents, like fat, phosphatase, or glycogen; the phase-contrast microscope and the possibilities it gives for studying living cells; the electron microscope; the use of polarised or ultraviolet light, and so on. The unusual bulk of Dr. Bessis's book is accounted for by the wealth of illustrations, which show appearances with classical techniques, cytochemical techniques, and phase-contrast and electron microscopy, as applied to almost all types of cells. There are no fewer than 405 text figures—mostly photographs—and 22 colour plates of notably high standard.

Details of these techniques are followed by a short section on the general physiology and pathology of blood-cells, which deals with systems of hæmopoiesis, quantitative matters like normal "myelograms" and "splenograms," and abnormalities observed in fixed and living cells, like vacuolisation and ageing. The bulk of the book is a detailed study of each "line" of blood-cells, illustrated by all the techniques used. This section incorporates most of the material that was previously published in Dr. Bessis's smaller book, *Cytologie sanguine, normale et pathologique*, which appeared in 1948; and most of the colour plates of abnormal hæmopoiesis are reproduced from that volume. The other illustrations are considerably more numerous and the text has been extended. At the end of each chapter is a good bibliography, showing that Dr. Bessis is familiar with world publications on hæmatology.

Those who have studied Dr. Bessis's contributions to the medical press will find little new in this book, but for others it presents a unique compendium of information on the application of the newer cytological techniques to the study of blood-cells. It is fair to say that, so far, none of these new techniques has proved superior to the established ones for the diagnosis and control of disease, and they are therefore of little more than academic interest to the clinical pathologist. The research-worker, however, may well get help from cytochemical techniques, and in particular from the phase-contrast microscopy of living cells. In this book he will find a guide to what he can expect to see in human blood and marrow cells.

Acute Anuria

Study Based on Renal Function Tests and Aspiration Biopsy of the Kidney. CLAUS BRUN, 3rd medical department, Kommunehospitalet, Copenhagen. Copenhagen: Munksgaard. 1954. Pp. 215. D. kr. 30.00.

In this book, a well-known Danish nephrophile reviews the subject of acute anuria in relation to 32 patients whom he has treated and investigated. The historical aspects of our knowledge of anuria are well reviewed, but much of this work has been outdated by changes in terminology, and (more important) by the recent functional studies of Bull, and the morbid anatomical observations of Oliver.

By comparison with the results attained by Oliver's micro-dissection technique, the renal biopsy specimens obtained by Brun are uninformative. Most of the patients were treated conservatively, but intestinal dialysis and even exchange transfusions were used in a few patients; no assessment of the value of such measures is possible, because of the uncertain case-prognosis of this condition. Brun departs from the Bull régime by correcting obvious electrolyte abnormalities, and claims that the clinical improvement outweighs any increased risk of pulmonary œdema; but this is at present rather an open question, in view of the finding of Hamburger and Mathé that cellular overhydration may exist, and be corrected by saline administration. There is no discussion of the use of exchange resins for lowering serum-potassium concentration, or of the possibility of giving hypertonic glucose solutions by polythene catheter into the great veins when patients are unable to tolerate a high-calorie régime by mouth.

This account of anuria is rather diffusely written, and better reviews for the general physician are available (such as that by Swann and Merrill¹); but specialists in kidney disease will find many of Brun's observations, and especially the detailed case-reports, of great interest.

Carbohydrate Metabolism

Symposium on the Clinical and Biochemical Aspects of Carbohydrate Utilization in Health and Disease. Editor: VICTOR A. NAJJAR. Baltimore: Johns Hopkins Press. London: Oxford University Press. 1953. Pp. 134. 32s.

THIS is a record of the papers read at a conference on the clinical and biochemical aspects of carbohydrate utilisation in health and disease. Many distinguished researchers contributed to the symposium, which was designed not for their mutual interests but for those of the clinician.

In general three main aspects of carbohydrate metabolism are considered—the enzymatic constitution of the individual, the hormonal balance, and the electrolyte pattern in the extracellular and intracellular fluid. Subjects covered include glycogen storage disease (4 types), the effects of hormones on enzymes, hypoglycæmia, including the rare variety associated with hypoplasia of the pancreatic α -cells, the diabetogenic effects of potassium depletion, and the optimal electrolyte replacement for diabetic ketosis. There are unfortunately confusing mistakes in the labelling of two of the diagrams, but the contributors deserve much credit for having compressed so much of interest into so few pages.

Practical Mycology

Manual for Identification of Fungi. SIGURD FUNDER, DR. PHILOS. Oslo: Brøgger's Boktrykkeri. 1953. Pp. 146. 39s.

THIS recent addition to the growing list of books on mycology for medical readers can be strongly recommended—either as a simple but entirely satisfactory introduction to the subject, or as a guide to those, not contemplating the special study of mycology, who wish to identify the types of microfungi encountered in routine laboratory work. The biology of the microfungi is adequately explained and mycological technique and methods of examination, as well as the basis of classification, are clearly set out.

A large section on the identification of fungi by microscopy contains an atlas of good line drawings illustrating the characteristic morphology of genera and species, with notes on their systematic position. This section is in three parts, the first of which deals with fungi of general interest, the second with the medical fungi in both saprophytic and parasitic life (with a dichotomous key to the human mycoses), and the third with fungi of importance in plant pathology. A schematic classification of the Thallophyta and a useful glossary of mycological terms complete the work.

Essays on the Applied Physiology of the Nose (2nd ed. St. Louis, U.S.A.: Annals Publishing Company. 1953. Pp. 452.)—In a note on the second edition of his well-known essays, Dr. Arthur W. Proetz says: "What can be said of a second edition but that it is the first—revized, amplified, modernized and embellished to the utmost of the author's resources and abilities?" The book has been amplified by some 50 pages and revised, modernised, and embellished mainly by many excellent new diagrams, and descriptions of equipment and experiments, prepared by the author himself. The general plan of the book is almost unchanged, except for a considerable expansion of the chapter on nasal air currents. Most of this new work was presented at the Royal Society of Medicine in Dr. Proetz's Semon lecture for 1952. It includes an account of the "impingement areas" of the air currents and their close correspondence with the lymphoid patches of Waldeyer's ring. Dr. Proetz's work is very well known to rhinologists and physiologists in this country, and this is a welcome revision of one of the few classical monographs on the subject.

Modern Practice in Anæsthesia (2nd ed. London: Butterworth. 1954. Pp. 622. 65s.)—In preparing the new edition of his excellent textbook Dr. Frankis Evans has made substantial changes. The chapters on anatomy and physiology and on relaxants have been rewritten, and new material on cardiology and on saline infusions and blood-transfusions has been added. The chapters on apparatus and on machines for controlled respiration perhaps follow the manufacturers' leaflets too closely and might be rewritten on broader lines, or omitted, in the next edition. As a whole, however, this is one of the best general textbooks of anæsthesia in the English language.

These are important features!

- ★ Rapid and intense antibacterial activity even in the presence of blood, pus and other tissue fluids.
- ★ Less tendency than antibiotics and sulphonamides to give rise to resistant pathogenic strains.
- ★ Minimal tendency to provoke sensitization reactions.
- ★ Unimpaired activity against many organisms resistant to antibiotics, acridine compounds and other anti-infective agents.
- ★ Stable under normal conditions of use and storage.

And these are the properties which immediately recommend 'Brulidine' as the ideal preparation for topical application in the prophylaxis and treatment of superficial mixed infections common to wounds, burns, ulceration and certain skin conditions.

IRON WITHOUT IRRITATION

'Fergon' (ferrous gluconate) does not produce the gastro-intestinal disturbances often associated with iron therapy. This is particularly valuable in hypochromic anæmia of pregnancy since patients who cannot tolerate other iron preparations are able to take 'Fergon' without discomfort. Absence of irritant effects also ensures maximum absorption and utilisation of iron with a consequently rapid rise in the hæmoglobin rate.

PACKINGS: tablets gr. 5 in bottles of 100 and 1,000; liquid (6%), for infants and young children, in 4 oz. and 80 oz. bottle.

Medical literature and sample on request

* The reduced basic N.H.S. cost of one week's treatment with 'Fergon' tablets is 8d. The basic N.H.S. price of 'Fergon' liquid is 3s. per 4 oz. bottle.

ALFICETYN *Chloramphenicol*

EAR DROPS

Having a wide range of antibacterial action and an exceptionally low sensitising potential, Chloramphenicol is the ideal antibiotic for topical use.

Alficetyn Ear Drops are indicated in the treatment of infections of the ear including chronic suppurative otitis media, chronic otitis externa and cavity infections following tympano-mastoidectomies and fenestration operations.

The reduction in time and effort to effect a cure in these conditions is most striking and Chloramphenicol applied topically in the form of Alficetyn Ear Drops is an advance on previous forms of treatment.

Treatment of Hyperthyroidism

IN the history of the treatment of hyperthyroidism four distinct periods can be distinguished. During the first, which lasted from the recognition of the disorder until about the end of the 19th century, no effective treatment was employed. The only agent available at that time which could have influenced hyperthyroidism favourably was iodine; but its use was virtually forbidden by the authorities of the day who all agreed on the danger of giving it to hyperthyroid patients. One of the few physicians bold enough to defy the ban was CHEADLE^{1 2} of St. Mary's Hospital: he reported excellent results with iodine, but the medical world was unimpressed. The second period started about 1900, when surgeons became interested, and a lead was given by KOCHER in Switzerland, the MAYO brothers in the United States, and DUNHILL in Australia and this country. At first a hemithyroidectomy was the usual operation, but experience showed that a more radical procedure was necessary if the symptoms were to be completely controlled. So the modern technique of subtotal thyroidectomy was gradually evolved, though it often had to be done in stages, sometimes preceded by ligation of thyroid arteries at a preliminary operation. The best surgeons achieved mortality-rates of 2-5%—a fine performance, for many of their patients were gravely ill. Nevertheless physicians looked on operation as a fairly desperate expedient to which they were driven only by the lack of any positive therapy of their own and by the high mortality of the untreated disease.

This second period lasted until about 1925, when the benefits of iodine, which had been gradually rediscovered during the previous fifteen years, suddenly became apparent to all. Within a year or two a substance which had been regarded as highly toxic to patients with hyperthyroidism was accepted as their salvation. This transformation benefited the surgeon more than the physician, for iodine proved unsuitable for long-continued treatment: usually the maximum improvement was obtained some two to four weeks after the start, and few patients could be satisfactorily controlled for an indefinite time. But iodine was ideally suited to the preparation of patients for operation, and surgeons found that in most cases they could now perform a one-

stage subtotal thyroidectomy. The popularity of the operation increased enormously and probably accounts for the steep rise in the death-rate from hyperthyroidism during the years between the wars. For, though the operative mortality in the best clinics fell to about 1-2%, the mortality in the country as a whole must have been much higher—how high nobody can tell. Hence for the hyperthyroid population as a whole the introduction of the standard iodine-prepared subtotal thyroidectomy was a mixed blessing. In the best clinics it was a very satisfactory procedure, resulting in rapid loss of symptoms, with relatively little danger or inconvenience. But often both iodine and operation were misused. Some patients were allowed to linger for months or years half-treated with iodine, and the surgeon was called in too late or not at all. In other cases the operation was attempted too hastily in a patient not properly prepared; and sometimes it was done without sufficient reason. The inter-war period also saw attempts to treat hyperthyroidism by X rays; but in general radiotherapy was not very successful, because it seldom influenced thyroid function without damaging the skin. There were probably some good results, but also a number of scarred necks and even an occasional skin cancer. The therapeutic response, when there was one, was slow and inferior to that obtained by subtotal thyroidectomy.

The final period opened after the late war, when the thiouracil drugs and radio-iodine appeared on the scene. For a time it looked as though one or other of these might supersede subtotal thyroidectomy as the standard means of treating hyperthyroidism. This they have not done; but their existence has on the whole been beneficial to surgery. For, though neither can improve on the best results of the best surgeons, they offer alternatives which are a good deal better than inferior surgery. And both have helped the surgeon directly. Anti-thyroid drugs of the thiouracil type, used judiciously and followed by iodine, can make the severest case euthyroid by the time of operation, without increasing the operator's difficulties. They are not needed in the milder cases: thus LANGE,³ reviewing work at the New End Clinic, says that of 781 cases 35% were prepared with thiouracil followed by iodine, and 65% with iodine alone. Radio-iodine relieves the surgeon of the technically difficult task of operating on cases of recurrent hyperthyroidism. Through these advances, and the concurrent improvements in anaesthesia, blood-transfusion, and antibiotics, operative deaths have almost disappeared from the best surgical clinics, and all can quote mortality-rates in terms of fractions of 1%. We must still, however, reckon with a certain amount of postoperative morbidity. Postoperative hæmorrhage is still seen sometimes, and surprisingly large collections of serum can appear in the wound, causing ugly scars if not promptly attended to. Occasional damage to the parathyroids is probably unavoidable, though the resulting tetany is seldom permanent; the recurrent nerve is divided from time to time, even by the most careful surgeons; and patients also tend to suffer from postoperative hoarseness even when these nerves are known to be intact. Remote consequences include myxœdema and recurrent hyperthyroidism—when too little or too

1. Cheadle, W. B. *St. George's Hosp. Rep.* 1869, 4, 175.
2. Cheadle, W. B. *Ibid.*, 1872, 7, 81.

3. Lange, M. J. *Brit. J. Surg.* 1953, 40, 544.

much thyroid tissue is left behind. Recurrent hyperthyroidism can be avoided at the risk of myxœdema, or vice versa, but no known procedure will obviate both.

Patients with hyperthyroidism can fairly be told that the risk of operation is almost negligible, and that complications are unlikely. If things are as well managed as they are at the New End Clinic,³ their stay in hospital need be no more than a fortnight, though presumably they will require two to four weeks' convalescence afterwards before returning to work. Most patients will agree that this is a reasonable price to pay for release from troublesome symptoms. Yet some will hesitate. As a general proposition, it can be said that patients dislike operations; and even a few weeks off work can sometimes dislocate a career or cause grave financial hardship. It is not always justifiable to urge a patient to have an operation when alternative methods of treatment exist, especially when the symptoms are no more than mild. Moreover, in some cases non-operative treatment is preferable on strictly medical grounds; for when exophthalmos threatens to become progressive it is often aggravated by an ill-timed thyroidectomy. In such cases cautious treatment with anti-thyroid drugs provides a more delicate control of thyroid function, though it must always be remembered that over-treatment with these drugs can be as disastrous to the eyes as surgery.

Although medical treatment does not demand any special technical skill, it does demand judgment and perseverance. Unlike the dose of thyroid required to control myxœdema, the dose of anti-thyroid drug required to control thyrotoxicosis is not constant, and neglect to change it with variation of the disease leaves the patient uncomfortably hyperthyroid on the one hand or hypothyroid on the other. The latter state is perhaps the more unpleasant for the patient, especially as it is accompanied by enlargement of the goitre. Such enlargement was not uncommon in the early period of thiouracil therapy, and led many physicians and surgeons to conclude that this type of treatment could not be satisfactory. But, as usually happens, further experience has led to a more delicate control of hyperthyroidism, and there is no reason why patients should not be kept indefinitely as fit as they would be after a thyroidectomy. Simultaneously the safety of medical treatment has improved—a very important matter, for if drug treatment is to compete with surgery it must be as safe as it can be made. The parent substance, thiouracil (particularly when used in the large doses at first thought necessary) was anything but safe. The toxic effects could all be attributed to hypersensitivity, perhaps due to the formation of a drug-protein complex which could act as an antigen. The more common reactions—rashes and drug fever—were fortunately not too serious; but agranulocytosis was often fatal, and there was the possibility that thiouracil might cause more distant reactions of the type of polyarteritis nodosa. Addition of a methyl or propyl group to the thiouracil molecule seemed to decrease the incidence of toxic reactions, and the introduction into clinical use of substances with a mercapto-imidazole nucleus (methimazole, carbimazole) has provided us with even more potent and less

toxic drugs. Nevertheless, even these refined products occasionally give rise to reactions, and agranulocytosis has lately been reported⁴⁻⁶ in 3 patients taking carbimazole, a drug which seemed safer than the others.⁷

It now looks as though no compound of the thiouracil type is incapable of inducing agranulocytosis; and the possibility of this complication—unpleasant out of proportion to its incidence, for it comes without warning and demands urgent action—deters many physicians from using thiouracil compounds at all. Hence it is well worth examining the claims now being made on behalf of potassium perchlorate, which both in chemical structure and in physiological action is entirely unrelated to thiouracil. Whereas thiouracil interferes with the actual synthesis of thyroid hormone, potassium perchlorate stops the process at an earlier stage by preventing the thyroid gland from concentrating iodide, which (unless the blood-iodide level is quite abnormally high) is an essential preliminary to such synthesis. First investigated by WYNGAARDEN et al.⁸ it was introduced into clinical use by GODLEY and STANBURY⁹ at the Massachusetts General Hospital, whose series of 24 cases afforded good evidence of its usefulness. In our present issue, Dr. MORGANS and Dr. TROTTER report their experience in a further 108 cases, and conclude that potassium perchlorate is an effective anti-thyroid agent, though not perhaps quite as potent as methyl thiouracil, even when given in larger dosage. To a few patients it seemed to be a gastric irritant, but no side-effects of the hypersensitivity type were seen. These preliminary results should encourage further study; and if it can indeed be shown that perchlorate is a drug without terrors the case for medical as opposed to surgical treatment will be greatly strengthened. But, however successful the new drug proves, it cannot do away with what is perhaps the greatest handicap of medical treatment—the length of time it takes. None of the present anti-thyroid drugs can cure hyperthyroidism; they merely control it until such time as the disease dies out of its own accord. This may take only a few months or it may take years; and in treating hyperthyroidism medically the quality most needed—by both parties—is patience.

The exact place of radio-iodine in the treatment of hyperthyroidism cannot yet be known. The great deterrent to its use is the fear that it may cause cancer of the thyroid. If it does so, the latent period between treatment and cancer is likely to be of the order of twenty years; so it will be another ten years or so before we can tell whether this fear is real or imaginary. Meanwhile it is already apparent that radio-iodine has the practical disadvantages that it is slow to act and that the right dose for an individual is hard to determine. For the present it is probably best reserved for two types of patient—namely, the elderly and those with hyperthyroidism which has recurred after thyroidectomy.

Balance

WE publish on p. 769 a memorandum by Sir RUSSELL BRAIN, as chairman of the Staff Side of Committee B of the Medical Whitley Council, announcing salary increases for hospital doctors. These increases arise out of the Danckwerts award, which, by raising the average income of general practitioners in the National Health Service, greatly reduced the financial advantage eventually obtainable by those who spend additional years in training to be consultants. The Government have been satisfied that this financial advantage must, in some degree, be restored; and they are therefore prepared to find the sum of over £3 million that will be needed to raise the salaries of the younger consultants by £400 a year (or the appropriate fractions for part-time posts), and those of senior hospital medical officers by £200, with smaller increases for registrars and for housemen. The new scales will not satisfy those who hold that consultants and specialists should be content with nothing less than the 100% increase on Spens 1939 figures which general practitioners succeeded in gaining through arbitration. But Sir RUSSELL BRAIN makes it quite clear that the Government have refused from the first to reconsider consultant salaries on a basis of "betterment," and have been equally firm in refusing arbitration; and in view of the consequences, both inside and outside the National Health Service, that would follow a rise of anything approaching 100% in consultants' salaries we believe that in taking this line the Government are right. The task of administration is rather to remove anomalies than to create new ones; and on this occasion the Treasury has recognised the needs of the situation and has responded to practical arguments in a practical way. As for the distribution of the money, there will be some who think it should be different in one way or another. But, since the main object of the adjustments is to induce suitable candidates to make the sacrifices and take the risks involved in seeking consultant status, there are sound reasons for giving the chief increase to those who attain it. For our part we by no means exclude a revision of the present system of grading; for we believe that the status of consultant should be reached through that of specialist—a new rank which should include those now called senior hospital medical officers. But the new scales of remuneration need not stand in the way of this reform, and we congratulate both sides of Whitley Committee B on their sensible settlement of a difficult issue. In these congratulations it would be fitting to include Lord MORAN, who from the moment of the Danckwerts award has insisted that consultants' salaries must be revised so as to correct the imbalance the award created. At a time when most of us were only rejoicing that the general practitioner had been rescued from the position of poor relation, his arguments fell mostly on deaf ears; but their validity became evident when the actual remuneration of specialists at various levels was dispassionately examined. As between specialist and general practitioner, the scales, which had been tilted too far in one direction before the award, were tilted too far in the other direction after it. We may fairly hope that with the present adjustments equilibrium has been reached.

Annotations

VENOUS THROMBOSIS IN THE LEGS

SINCE the 1930s when anticoagulant drugs were introduced into clinical practice, venous thrombosis of the lower extremities has been closely studied. This complication develops most usually after surgical operations or parturition, and less commonly after local trauma. Of the many factors that may favour thrombosis, those which have received most attention are inactivity of the legs from confinement to bed and restriction of respiratory movements owing to pain (both of which may impede return of blood from the lower extremities), injury to the lining of the veins by prolonged pressure on the operating-table, and direct spread of infection in cases of pelvic inflammation. The circulation may be further impaired by lowering of blood-pressure from shock and hæmorrhage. The success of efforts at prophylaxis—by exercises in bed, early ambulation, and control of infection by antibiotics and of shock by transfusion—is difficult to estimate, partly because minor cases often pass unnoticed, and partly because the relative importance of the various suspected ætiological factors cannot be evaluated precisely. Certainly these methods have not eliminated postoperative and postpartum thrombosis even if they have appreciably diminished its incidence. Anticoagulants have proved useful in relieving symptoms and in hastening resolution, but they have not sensibly diminished the incidence of pulmonary embolism, or of the postphlebotic disturbances of the venous circulation that lead to chronic œdema and ulceration.

Particular interest therefore attaches to recent studies of cases of thrombophlebitis which have hitherto been termed "spontaneous" and received scant attention. Arising under apparently normal conditions of life, these cases may be a more profitable field for the study of ætiology than is found in the complexly abnormal postoperative state. Homans¹ reports three cases in which thrombosis developed after long journeys by aeroplane or motor-car. Two of the patients were middle-aged men, one of whom had previously had a thrombosis of his femoral artery and venous thrombosis, and the third patient was a 19-year-old girl who also had had a femoral-vein thrombosis. Homans infers that the prolonged maintenance of the sitting posture in these cases was the cause of the thrombophlebitis. He ascribes two further cases to long hours spent at a desk, and to two hours at a theatre with the legs crossed. Homans suggests that people over fifty years of age should move their toes, feet, and lower legs when sitting for long periods and should get up and move about when opportunity offers.

Other lines of approach to so-called "spontaneous" venous thrombosis have yielded more definite information. Hubay and Holden² report that of eight patients admitted to hospital with peripheral venous thrombosis, seven had occult neoplastic lesions and one had tuberculosis. These workers suggest that blood-coagulation may be affected by the physiological response to necrotic tissue. Though admitting that they have seen many patients with venous thrombosis in whom no associated lesion was detectable, they hold that this disorder should alert the clinician to the possibility of an obscure visceral neoplasm. Wegelius³ studied 178 cases of deep venous thrombosis in the lower limbs in the medical wards of the Maria Hospital in Helsingfors. 44% of the patients had congestive heart-failure, 13% diseases of the blood, and 15% infection (generally of the respiratory tract). Like Hubay and Holden, Wegelius notes an association of venous thrombosis in the lower limb with malignant tumours (3.3%), principally of the pancreas or lungs. In 6% of cases no

3. Wegelius, O. *Acta med. scand.* 1954, 148, 27.

cause was found. Wegelius found no convincing evidence for the view that the administration of digitalis and mercurial diuretics increases the coagulability of the blood, nor for the claim that erythrocyte aggregation is a major factor in the aetiology of thrombo-embolism.

Clearly we do not know why a person develops deep-vein thrombosis in the legs, whether after operation or parturition, or when he has some "internal disease," or when in apparently normal health. Thus prophylaxis must remain empirical and imperfect. The combined efforts of surgeons, obstetricians, physicians, and pathologists are needed to lighten our darkness.

BEACH POLLUTION

NOT long ago we commented on the risks to the public health which arise from the common practice of discharging untreated sewage into the sea.¹ If the outfall be extended far enough out to sea and consideration be given to the set of tide and current little harm will result, but only too often pollution of a bathing beach may be discovered not by bacteriological finesse but by sight and smell. While coliform bacilli of the types found in the human bowel are rare or absent in water sampled offshore, they are usually to be found in coastal waters. It is true that enteric infections due to bathing beyond reasonable doubt are few, but it would be unwise to deny that the risk exists. Questions of health apart, we do not doubt that the presence of human faeces on the beach brings a resort into popular ill repute. This subject therefore affects not only medical officers of health and sanitary engineers but all those who depend for their living on the seaside holiday trade.

Our French colleagues have shown much interest in these problems and, among other things, have established that what was known to be true of the water is equally true of the fish in it: faecal bacteria are common in the viscera of fish taken in coastal waters but absent from those caught offshore. Guelin,² working at the Plymouth Marine Biological Laboratory, has now shown that specimens of *Olenolabrus rupestris* (a little wrasse vulgarly known as the pink bream or Jago's goldsinny) which were allowed to swim for an hour in a tank containing *Escherichia coli* continued to harbour this organism for no more than six days after their removal to clean water. Bacteriophages inoculated in the same way persisted for an even shorter time. These were elegant experiments, but we cannot allow the author's claim that they prove that the intestinal flora of warm-blooded animals cannot adapt itself to life in fishes. There are fish and fish, and what may be true in a pink bream may not apply to the whole order of Pisces. Man and guinea-pig are both mammals, but the bacterial contents of the intestines are quite different.³ One way or another these observations cannot have much bearing on public health since, except for the genitalia and the livers of some larger pelagic fish, fish offal is not an article of diet. One other incidental observation by Guelin calls attention to a technical method of tracing enteric infection which is little used here but which seems to give good results in France. He found bacteriophages of *Esch. coli* in several parts of Plymouth Sound but the phage of *Salmonella paratyphi-B* once only, and that by the outfall of a sewer. The phages of *Salm. typhi* were not found—which contrasts with his experience on the Mediterranean coast.

An inquiry by Moore⁴ into the practical aspects of beach pollution in an anonymous resort in the West of England has produced a notable paper. Sporadic infections by *Salm. paratyphi-B* spread over several years culminated in 1946 in an epidemic attacking 21 people out of a population of about 5000. Popular blame for this accident fell on the town sewage which was discharged

on the beach at all states of the tide, but careful investigation showed that at least half the sufferers had not even paddled. Two years later *Salm. paratyphi-B* was found constantly in the sewer, and this was traced to the wife of the local vendor of ice-cream whose wares had been eaten by 20 out of 21 people infected. Despite this discovery the beach was suspect as the origin of the illness of the 21st patient—a child whose fond parents regulated his diet more strictly than his bathing. A bacteriological survey of water and of sand from between the tide-marks showed that coliform bacilli (including "faecal coli") could be found over the whole 8000 feet of beach, and, as might be expected, they were in general more abundant near the outfall of the sewer. Observations on the tidal currents by means of marker-floats showed that while the general set of ebb and flood was along the shore this was not true throughout the tidal cycle. The presumptive coli count of the water was influenced by these tidal anomalies and by weather conditions. On the basis of these findings the local authority decided to make some alterations in the outfall. It was moved some distance laterally and extended seaward, and advantage was taken of a tidal set away from the shore during the first hour of the ebb to arrange that discharge should be limited to this period. Bacteriological tests when the new plant was in operation did not show a beach free from faecal pollution, but, whereas in the earlier series 35% of samples had shown more than 1000 organisms per 100 ml., after the improvements the figure had fallen to 9.2%.

As in so many problems of public health, the ideal solution demands an almost bottomless purse; but Moore's results suggest that studious and imaginative reconnaissance may lead to great improvements at a small outlay. This paper is indeed a model of method and should be read with care by the health authorities of seaside resorts big and small. The risks to health of beach pollution may be slight; but so long as an uninoculated population has the opportunity of access to human faeces (or its end-products) which may contain *Salm. typhi* or *Salm. paratyphi-B*, so long will enteric fever be found in the Registrar-General's tables.

LYMPHŒDEMA

MUCH concerning lymphœdema præcox remains obscure, but Kinmonth and Taylor¹ have greatly improved our understanding of the condition. Like earlier investigators these workers found that phlebographic and venous-pressure measurements were consistently normal, and it may therefore be presumed that the cause of the swelling does not lie in abnormal venous hæmodynamics. In every case intradermal injection of a highly diffusible dye (patent-blue v) revealed a network of abnormally dilated lymphatics. In some cases where large lymphatics could be exposed surgically after their detection by dye, a cannula was inserted and X-ray contrast medium (diodone) injected. Radiographs revealed dilated and tortuous lymphatics passing upwards through the femoral region into the abdomen. The lymphatics distal to the injection site were also incompetent and valveless. When 2-3 ml. of patent-blue was injected subcutaneously and intramuscularly in a normal limb and the site of injection massaged, normal beaded vessels about 1 mm. in diameter were seen lying near the deep veins. In lymphœdema the lymphatics were dilated and incompetent, and this normal transmission of dye was absent. Information about the efficiency of lymphatic circulation can also be obtained by injecting into the superficial tissues protein labelled with radioactive iodine and measuring the time taken for its removal from the injection site. Kinmonth and Taylor found that the removal-rate on ambulation in two normal people was about ten times that in two lymphœdematous patients.

1. Kinmonth, J. B., Taylor, G. W. *Ann. Surg.* 1954, 139, 129.

The cause of this abnormal dilatation of the leg lymphatics is not clear, but it seems possible that it is essentially a congenital malformation. Operations for the relief of lymphoedema have been designed either to bridge by skin pedicles what was assumed to be a barrier to lymphatic circulation,² or to excise the mass of redundant subcutaneous tissue in an effort to make the limb more shapely and efficient. If, as now seems clear, the underlying disorder is enlargement and incompetence rather than obstruction of the lymphatics, a different approach may be adopted—namely, ligation of abnormal channels in the femoral region in the hope that lymph will return by alternative and more competent routes. Kinmonth and Taylor treated one patient in this way without success; the operation they found most suitable was superficial lymphangiectomy, whereby the cedematous subcutaneous tissue is excised and the exposed muscles covered with free skin grafts which can be most readily prepared by means of an electric dermatome.³ But this major operation should not be undertaken unless the patient is greatly handicapped.

THE MUSCULAR DYSTROPHIES

CLASSIFICATION of the progressive muscular dystrophies has been complex and unclear. The clinical literature is a wilderness of eponyms, and though it is generally held that the disorders are of hereditary origin the genetic background has remained confused. Professor Becker, in a new monograph,⁴ analyses the clinical and genetic bases and tries to correlate them. Though the multiplicity of the clinical forms is recognised, and though it is known that the heredity factors vary, there has been a tendency to regard the different forms as manifestations of a single clinical entity. Becker thinks that this over-simplifies the problem, and finds evidence of two separable clinical entities with three separate genetic streams.

The clinical material surveyed comprises 104 families—most of them belonging to the South Baden district surrounding Freiburg—collected between the years 1904 and 1941 in the various clinics of Freiburg and district. These families contained 259 patients affected by muscle dystrophy, and the total genealogical investigation runs to 6238 persons. Becker has himself examined 159 of the affected patients and interviewed 1844 members of the families. The two clinical forms which he distinguishes are: (1) a shoulder-girdle, or descending form, in which the first or major disability is in the upper limbs, though it may later spread to the lower limbs; and (2) a pelvic or ascending form where the reverse takes place. The two forms never appear together in a single family, and so it follows that they are clinically and genetically distinct. In the descending form there is discernible a definite dominant hereditary pattern; but in addition there are a large number of isolated cases thought to be caused by an unknown, but possibly traumatic, exogenous factor. The pelvic, or ascending, form exhibits two lines of inheritance: the first of these (accounting for a number of isolated cases) is a simple recessive, while the second is a sex-linked recessive. Becker seems to be a little doubtful about this particular concept, since he is constrained to say that the recessivity of the sex-linked gene is not quite regular. Nevertheless, he is able to approach his review of previously published cases with confidence, and to show that in 50 of the 54 families displaying a dominant heredity which have been reported, the cases were, in fact, of the shoulder-girdle type, while of 41 families with sex-linked recessive characters 39 had the pelvic

type of dystrophy. These figures seem impressive, and support the conclusion that there are three independent lines of inheritance.

In the descending (shoulder-girdle) form—which of course may include the face, as in the Landouzy-Déjerine clinical subgroup—the age of onset is between 7 and 25 with a peak at 15; the sex-linked ascending (pelvic) type begins in the first 3 years of life; while the non-sex-linked (or autosomatic) ascending form is most liable to develop in the third decade. The three types vary in prognosis too. The descending form is slow and mild, with a lengthy course, and the patients are economically self-supporting. The sex-linked ascending type progresses rapidly and reaches the upper limbs within the first 10 years; the patients usually die by the age of 20, and rarely enjoy any school life, being gravely disabled throughout. The recessive autosomatic ascending form has a much more protracted course and is milder. The patients can usually manage to get about and the expectation of life is not greatly reduced. The dominant descending form tends to be a pure muscular affection, whereas the other two may show disturbances both of fatty tissue and of bone. More rarely genital underdevelopment may be seen, and so may mental defect.

The logical analysis of a complex problem sometimes leads to a charge that the analyst is attempting to tidy up reality; but that is not the case here. In this clear and thoughtful exposition of a thesis based on a wide survey of genetic and clinical material Becker provides a valuable scaffolding for the further clinical and genetic assessment of the muscle dystrophies.

PYRAZINAMIDE IN TUBERCULOSIS

PYRAZINAMIDE was synthesised during the investigations that followed the discovery of the antituberculous activity of nicotinamide. It was found to be only moderately active against the disease in mice¹ and guinea-pigs.² In liquid culture media it inhibited tubercle bacilli only in relatively high concentrations³; and on solid media it appeared to have little or no action.⁴ But the first trials in man suggested that its activity was greater than might be inferred from the laboratory results.⁵ The effect, however, was short-lived; many patients relapsed early in the treatment, and decreased bacterial sensitivity was common. Treatment with pyrazinamide and isoniazid together seemed more promising⁶; and McDermott et al.⁷ have now discovered some interesting experimental evidence of this enhanced effect of the two drugs.

They studied the action of several antituberculous drugs by enumerating the viable tubercle bacilli in the spleens of infected mice. Isoniazid causes the population to fall immediately; but it then remains constant despite continued treatment. Pyrazinamide produces a similar change. But with the two together the fall continues rapidly until bacilli can no longer be detected. In mice pyrazinamide and isoniazid have an antibacterial action that is qualitatively different from that produced by any of the standard drugs used singly or together. McDermott et al. treated 61 patients with this combination for three to six months and then continued with isoniazid alone. The radiographic results were better, in their opinion, than in a similar group treated with isoniazid alone. All patients had a positive sputum before treatment; but after six months tubercle bacilli

were cultured from only 4 (7%) of 53, and three of the four strains were still sensitive to isoniazid.

McDermott et al. compare their results with those obtained with various combinations of streptomycin, *p*-aminosalicylic acid, and isoniazid in the United States Public Health Service investigations. Pyrazinamide and isoniazid seemed to give better radiographic and bacterial results than any of the others. The frequency with which bacterial resistance emerges depends both on the combination of drugs and the type of disease. Differences between two groups cannot, therefore, be attributed to the treatment unless the character of the disease is very similar in the two treatment groups. It would therefore be unwise to claim on the present evidence that pyrazinamide with isoniazid is the most efficient combination so far discovered. But the good results in man, together with the unique quality of its action in mice, certainly indicate that the combination should be more thoroughly investigated. Unfortunately, pyrazinamide may cause hepatitis. McDermott et al. noted impaired liver function in 6 of 66 patients who received the two drugs for eight weeks or more; 4 were jaundiced, and 3 of these became severely ill, 1 dying eight days after the first toxic signs. The drug had been given in daily doses of 50 mg. per kg. body-weight. Hepatitis has also been reported with daily dose of 2.8 and 3 g.,^{8,9} the incidence among the 159 patients in the four reports being 7% with 1 death. This seems to justify the conclusion of McDermott et al. that it is inadvisable to administer pyrazinamide with isoniazid in such high dosage as hitherto.

NEUROLOGICAL SEQUELÆ OF INOCULATION

SINCE 1950¹⁰ attention has repeatedly been drawn to poliomyelitis developing within four weeks of inoculation with diphtheria toxoid and/or whooping-cough vaccine; and in the past few weeks our correspondence columns have borne witness to what Dr. Ann Ferguson (March 27) calls the "increasing awareness of the connection between paralytic poliomyelitis and injections of all kinds."

It is timely, therefore, to have Miller and Stanton's¹¹ review of other occasional neurological complications of prophylactic inoculation and serum administration. Of these, the best recognised are the sequelæ of serum administration, which are usually accompanied by serum-sickness but occasionally develop without constitutional symptoms about the seventh to tenth day after injection. The commonest syndrome is pain around one or both shoulders lasting for a few days and followed, as the pain passes off, by atrophic paralysis; the muscles most usually involved are those supplied by the fifth and sixth cervical roots. Considerably less common are generalised polyneuritis, myelitis, and cerebral and meningeal involvement. The same type of neurological complications may develop two to four days after T.A.B. inoculation; but Miller and Stanton point out that radicular involvement is relatively considerably commoner after administration of serum, and meningo-cerebral and spinal-cord involvement after inoculation with T.A.B. With the exception of anterior poliomyelitis, neurological complications after diphtheria immunisation seem to be very rare; Miller and Stanton record transverse myelitis with a lymphocytosis in the cerebrospinal fluid developing eleven days after an initial injection of 0.2 ml. of alum-precipitated toxoid; and they cite three reported cases—one of cervical radiculitis after the fourth injection, one of motor polyneuritis, and the third of hemiparesis. The position is rather different with whooping-cough immunisation. Here neurological complications, other than poliomyelitis,

are always cerebral; several deaths have been recorded^{12,13} and there have been permanent neurological sequelæ in the form of epilepsy, mental defect, and hemiplegia. Neurological accidents in the prophylaxis of rabies have usually been ascribed to the injection of animal nervous tissue. They occur ten to fifteen days after the first injection and take various forms; the most serious is encephalomyelitis, while ascending polyneuritis and lesions of single peripheral nerves have also been found.

It seems to be established that the basis of serum-sickness is an anaphylactic reaction affecting in particular the blood-vessels; and probably the neurological sequelæ of serum administration have a similar basis, though it is not clear why in some cases the cervical nerve-roots are involved while in others the disturbance is more central. Prophylaxis against rabies involves repeated injections of brain emulsion, and the encephalomyelitis that occasionally ensues is probably an allergic disorder; in some ways it resembles the "allergic" encephalomyelitis produced in monkeys by injection of heterologous brain tissue emulsified with adjuvants. Miller and Stanton suggest that the complications of T.A.B. and whooping-cough immunisation may also be due to allergy, and that the sequelæ of a particular prophylactic inoculation appear to be similar in distribution to the neurological complications of the infective disease concerned. As regards whooping-cough there seem to be some grounds for this suggestion; but as regards enteric fever and diphtheria the connection is far from distinct.

Clinical syndromes similar to those recorded after serum administration or inoculation may develop spontaneously or after non-specific infections. The radicular involvement is exactly comparable to that described by Spillane¹⁴ in 1943 as localised neuritis of the shoulder-girdle (in a series where injection was not regarded as an important factor), and to the 136 cases reported by Parsonage and Aldren Turner¹⁵ under the name of neuralgic amyotrophy; while comparable polyneuritis and encephalomyelitis may occur without obvious precipitating cause. If, as seems very likely, Miller and Stanton are right in suggesting that an allergic reaction in the central or peripheral nervous system is responsible for the cases following administration of serum or inoculation, it is at least possible that a similar mechanism accounts for the "spontaneous" cases.

THE VENOMOUS WASP

NATURE has endowed the common wasp (*Vespa vulgaris*) with a formidable pharmacological armoury. Jaques and Schachter,¹⁶ in a careful study, have isolated from wasp-venom histamine, 5-hydroxytryptamine, and a third potent contractor of smooth muscle which they believe may be identical with bradykinin. These substances were found in large amount; histamine, for example, constituted 2% of the soluble matter in the venom—a concentration far higher than this widely distributed substance is known to attain elsewhere in Nature. Further, some wasp-venoms provoke release of histamine in the skin of the stung one; and all the venoms were found to contain large quantities of hyaluronidase. Thus science makes sense of our readiness to treat *Vespa vulgaris* with distant respect.

Dr. THOMAS CARNWATH, deputy chief medical officer at the Ministry of Health from 1935 to 1940, died on April 2 at the age of 75.

Mr. ARNOLD WALKER has been re-elected chairman, and Prof. A. A. MONCRIEFF vice-chairman, of the Central Midwives Board.

REMUNERATION OF HOSPITAL MEDICAL STAFF

A statement by Sir RUSSELL BRAIN as chairman of the Staff Side of Committee B of the Medical Whitley Council

1. NEW INCREASES AGREED

Committee B of the Medical Whitley Council have reached agreement on increases in the rates of pay of hospital medical staff which have been in operation since 1948. The agreement, which has effect from April 1, includes the following provisions:

- (1) The basic scale for consultants is to be £2100 rising by annual increments of £125 to £3100. This new scale gives an increase over the 1948 scale of £400 at the minimum and of £350 at the maximum.
- (2) The new basic scale applies to consultants with C distinction awards, who therefore obtain the same increase as consultants without distinction awards.
- (3) The increases for consultants with B and A distinction awards are, however, limited to £150 and £50 respectively.
- (4) The basic scale for senior hospital medical officers is to be £1500 rising by annual increments of £50 to £1950, an increase of £200 over the 1948 scale.
- (5) Senior registrars will receive £1100, £1200, £1300, or £1400 according to their year of service, an increase of £100 over the 1948 rates.
- (6) Registrars will receive £850 or £965 according to their year of service, an increase of £75 over the 1948 rates.
- (7) Junior hospital medical officers will receive a scale of £775 rising by annual increment of £50 to £1075, an increase of £75 over their 1948 scale.
- (8) Senior house-officers will receive £745, an increase of £75 over their 1948 salary.
- (9) House-officers are to receive an annual rate of £425 for the first, £475 for the second, and £525 for the third and subsequent posts (an increase of £75 over the 1948 rates), but the annual charge made to them for residence is to be increased by £25.
- (10) A maximum of $\frac{3}{4}$ of a session is to be placed on the weighting that part-time consultants and senior hospital medical officers are allowed when their salaries are calculated. This replaces the present maximum weighting of $1\frac{1}{4}$ sessions.
- (11) There is a protection against any individual losing pay on the coming into operation of the new agreement.

The details of the new arrangements are being worked out by the two sides of Committee B, and the full agreement will be transmitted to the Minister of Health and the Secretary of State for Scotland as soon as it is ready.

These increases are the final outcome of lengthy negotiations, and should be judged in the light of the following background and history of events.

2. HISTORY

Before the introduction of the National Health Service it was agreed that the range of remuneration for both general practitioners and consultants in that service should be determined by two Inter-departmental Committees, both under the chairmanship of Sir Will Spens. The Minister of Health and Secretary of State for Scotland on the one hand, and the profession on the other, agreed to accept the recommendations of these committees which became in effect the basis on which professional income in the National Health Service was fixed.

The recommendations of the Spens Committees were framed in terms of the 1939 value of money, and both committees explicitly stated that they left it to others to make the necessary adjustment to present-day values, such adjustment to have regard not only to changes in the value of money, but to increases in income which had in fact taken place in other professions since 1939.

The Consultant Spens Committee went further and stated that the adjustment should have regard to changes in income in other branches of the medical profession.

The Consultant Spens Report was not published until May, 1948, and when the National Health Service was introduced in July of that year hospital staff entered the new service on interim terms, relying on the assurance that the Minister had accepted the findings of the Spens Committee and would incorporate them in the new terms of service.

Subsequently the Government submitted the draft terms of service for hospital staff which, although following the recommendations of the Consultant Spens Committee, applied to them the same betterment factor as was given to general practitioners (20%). This betterment factor of 20% was not accepted by the profession as being an adequate or realistic adjustment of the 1939 figures to post-war conditions, and as early as January, 1949, a deputation from the Joint Consultants Committee and the General Medical Services Committee made joint representations to the Ministry on the subject. The Ministry's attitude at that time was wholly influenced by the white-paper on National Expenditure, and it declined to make any upward adjustment to the betterment factor.

In July, 1949, following discussions on the terms and conditions of service for hospital medical staff, the Joint Committee received certain assurances from the Ministry, among which were the following:

1. That no changes would be made in the terms and conditions of service without discussions in the appropriate part of the Whitley machinery.
2. That remuneration was regarded as a subject suitable for arbitration.
3. That save in exceptional circumstances, and after the conciliation machinery of Whitley had been exhausted, issues of remuneration remaining in dispute would go either to arbitration or for inquiry and report by a committee.

Thereupon the Joint Committee advised hospital staff to accept permanent contracts on the basis of the terms and conditions of service then offered.

Meanwhile there was growing unrest amongst general practitioners about the inadequacy of the capitation fee, and after prolonged negotiations the Ministry in October, 1951, agreed to refer the question of the size of the Central Pool to arbitration, on the understanding that whatever the result of the arbitration might be no additional monies would be paid unless agreement was reached upon a redistribution of the Central Pool. Mr. Justice Danckwerts was appointed adjudicator, and his award was published in March, 1952.

3. A CLAIM SUBMITTED

In June, 1952—shortly before Parliament approved the necessary supplementary estimate to implement the Danckwerts award—the Staff Side notified the Management Side of Committee B of its intention to submit a claim for increased betterment for hospital medical staff in the light of the Danckwerts award. At the outset of negotiations, and before detailed discussions had begun, the attention of the Staff Side was directed to the following statement by the Chancellor of the Exchequer in the House of Commons on 2nd July, 1952:

"I want to make it clear that the terms of reference of Mr. Justice Danckwerts' award were confined solely to the question of the remuneration of general practitioners in the National Health Service and his award has no wider application. In accepting the results of the adjudication, which was of an exceptional nature, the Government have by no means adopted the view that similar adjustments in other fields should follow. In their view there is no justification for any assumption that the appropriate standard of remuneration for the professional classes is a rate of 100% above that in

force in 1939. They consider that remuneration should be determined in the light of all relevant circumstances."

The Staff Side was left in no uncertainty as to the Government's policy in the matter and the attitude of the Management Side. It was quite clear that in no circumstances could a claim be considered for hospital staff based on the *Danckwerts award*, nor could there be any agreement to submit any such claim to arbitration.

4. LEGAL ADVICE SOUGHT

At this stage the Staff Side decided to take legal advice and consulted Mr. F. Grant, Q.C., who had presented the general practitioners' claim at the *Danckwerts* adjudication. Amongst other things Mr. Grant was asked whether there were arguments to support a legal claim that the Minister's promise to implement the recommendations of the Spens Committee was implicit in the contracts which consultants had accepted with hospital boards. After studying all the available files, records of past meetings with the Ministry, and other relevant documents, Mr. Grant reached the conclusion that the Staff Side had no claim which was enforceable at law. He did not think that it could be argued that an undertaking by the Ministry to implement the terms of the Consultant Spens Report was a part of the contract on which consultants entered the service. But even if it could be so argued the Minister could claim that the terms of the contract also included an agreement between the Minister and the consultants' representatives that a dispute about outstanding matters concerning the terms and conditions of service should be referred either to arbitration or to a committee of inquiry.

In view of the Government's known attitude towards arbitration, Mr. Grant pointed out that if negotiations broke down in Whitley, the Minister could fulfil his undertaking by referring all aspects of consultant remuneration to a committee of inquiry. The results of such an inquiry could not be foreseen, but one danger was that the findings could in effect replace the Spens Report as the basis of consultant remuneration for the future.

5. BASIS OF CLAIM

During the course of negotiations it became clear that while there was no question of departing from the Chancellor's statement on the application of the *Danckwerts award*, there seemed to be a realisation that the balance between general practitioner and consultant remuneration had been disturbed, that this factor alone might have an adverse effect on the future recruitment of hospital staff, and that a claim based on such considerations might well form a basis for discussion and possibly agreement. Thus the Staff Side was faced with two alternatives: either, despite the Chancellor's statement, to press its claim for a strict application of the *Danckwerts* betterment, or to examine the increases which general practitioners had in fact received as a result of the *Danckwerts award* and to see how far these had disturbed the balance of remuneration.

After very careful consideration the Staff Side reached the conclusion that it had very little choice in the matter. The Government, it was clear, had no intention of departing from the Chancellor's statement, and the profession, in spite of continuous pressure, has still been denied the right of unilateral arbitration. Again, because of the different methods of remuneration in general practice and consultant practice, a straightforward application of the *Danckwerts* "betterment" of 100% to the "Spens salaries" would have meant that a consultant aged 32 would start at £3000 p.a. and rise automatically to £5000. Again a consultant holding an A merit award would receive £10,000. Apart from the fact that a claim of this magnitude would have been

totally unacceptable to the Management Side, the effect would be again to upset the balance of remuneration between the two branches of the profession.

There were also the inescapable facts that the Government acceptance of the *Danckwerts award* had been conditional upon an agreed redistribution of general-practitioner income, and that the effect of the award, coupled with the redistribution scheme, had *not* been to increase the remuneration of *individual* general practitioners by 100%. For all these reasons the Staff Side considered that the only practicable course was to examine the effects of the *Danckwerts award* in the general-practitioner field and to relate them to the position of hospital staffs.

It accordingly looked at the percentage increases of remuneration received by general practitioners with varying sized lists, in order to compare them—so far as it was possible to do so—with hospital staff at different levels on the salary scales. Of necessity the comparison could not be precise because of the fundamental differences in the two methods of remuneration.

In the general-practitioner field the effect of *Danckwerts* had been that the most financially successful general practitioners, with the largest lists, gained virtually no increase of income; again, at the other end of the scale practitioners with very small lists received only a small percentage increase. Practitioners with medium-size lists, on the other hand, received the greatest benefit from the award.

It proved far from easy to translate the comparison into salary increases for hospital staff. The Staff Side felt, however, that, as in the case of general practitioners, if recruitment to the hospital service was not to be affected, the major benefit must be applied to the basic consultant grade in which the majority of hospital staff would make their permanent career rather than to the highest grades where, in any case, taxation would largely nullify the effect of any increase, or to the lower grades in which most practitioners would not expect to have their permanent career.

6. WHOLE-TIME CONSULTANTS

The Staff Side had for some time been pressing the Management Side to review the position of whole-time consultants in the light of the recommendation of the Spens Committee that, in addition to their salary, consultants should receive allowances to cover the expenses reasonably incurred by them in connection with their duties (e.g., car, telephone, membership of learned societies, and purchase of necessary textbooks). Few of these expenses had been met under the terms and conditions of service, and none of them adequately, and it was the intention of the Staff Side that in the claim for increased remuneration the opportunity should be taken of meeting the just grievances of the whole-time consultant.

The solution proposed to the Staff Side for meeting the whole-time consultant's difficulties was that, as part-time consultants and S.H.M.O.s were enjoying disproportionate advantages in the calculation of their salaries, the weighting of sessions should be entirely abandoned, all future part-time consultants and S.H.M.O.s and existing part-time men on promotion to a higher scale being paid unweighted elevenths of the full-time scale.

Apart from the fact that a proposal of this nature would not result in any addition to the whole-time scale, but merely a relative advantage at the expense of his part-time colleagues, the Staff Side felt that it would involve an abandonment of one of the vital principles of the Spens Report to which it could in no circumstances agree. After a very long discussion, the Staff Side agreed that a case had been made for modifying the Spens weighting which at 5 and 6 sessions rises to

$1\frac{1}{4}$ elevenths, and that a ceiling of $\frac{3}{4}$ eleventh for weighting should in future be applied. Existing hospital officers would however be fully protected against any loss of salary. Pressure will continue to be exerted on the Management Side to improve the allowances for whole-time consultants.

7. THE SPENS REPORT

The Staff Side is satisfied that the settlement it has achieved does in fact restore the balance between consultant and general-practitioner remuneration which was upset by the Danckwerts award. The differential increases now to be enjoyed by members of hospital staff are a result of a new system of distribution and are no more a departure from the Consultant Spens Report than were the differential increases enjoyed by general practitioners as a result of their new distribution scheme a departure from the General-Practitioner Spens Report. In the face of strong pressure to have it abolished, the principle of weighting for part-time consultants has been retained. The small modification agreed is but a part of the general redistribution of incomes.

The Staff Side is therefore satisfied that the agreement it has made with the Management Side in no way weakens the Spens Report as the basis of consultant remuneration. In their view Spens remains the yardstick of consultant remuneration, and either Side of Committee B is free to seek future adjustments in any grade, if experience shows that the present settlement is working unfairly.

8. CONSULTATION WITH THE PROFESSION

The Staff Side confidently hopes that hospital staffs will regard these increases as satisfactory. Consultants and other members of hospital staffs are, however, entitled to know why it was not found possible to consult them upon the outcome of the negotiations before agreement was reached. This is a difficulty which must always be faced when major issues are at stake. It is implicit in the Whitley machinery that representatives of both Sides have authority to negotiate and eventually to reach agreement. Failure to reach a settlement in Whitley without reference to the profession, would undoubtedly have led to the appointment of a committee of inquiry into the question of hospital staff remuneration in all its aspects. This would have delayed a settlement for a very long time and would not necessarily have led to a final agreement better than the one now reached. Moreover the Staff Side were told that, as an inquiry would probably follow any breakdown in negotiations, it was impossible for the proposed terms of a settlement to be made public, because, if they were rejected, the position of one or other party to the inquiry would be severely prejudiced.

Full consultation with the profession, even had it been possible, would therefore have meant interminable delays and possibly a hardening of the Government's views. Again the Staff Side was informed that one of the bodies represented upon it, the Central Consultants and Specialists Committee of the British Medical Association, had in July, 1953, passed the following resolution:

That the Central Consultants and Specialists Committee expresses its appreciation of the efforts of the Staff Side of Committee B, and of the Central Committee's representatives on the Staff Side, in the matter of the remuneration of hospital medical staffs, and gives such representatives full authority to agree, should they think fit, to such terms as the Staff Side can obtain; provided always that the principles embodied in the report of the Consultant Spens Committee are maintained, and that the committee's representatives will act without further reference to this committee only in case of necessity.

The Staff Side, being satisfied that its negotiations had safeguarded Spens and knowing that it could not refer the terms of the settlement to its constituent bodies,

none the less feels confident that the profession will agree that it took the right course in reaching agreement on the new increases. It realises that hospital staffs will be disappointed to find the increases in remuneration are not retrospective, but the Staff Side was convinced that insistence on retrospective application would have led to a complete breakdown in negotiations.

The Staff Side's task over the past eighteen months has been far from easy. It has had to press its claim during a period of national retrenchment and in the face of the Government's declared policy on the implications of the Danckwerts award. Only experience can show how far the increases obtained will improve recruitment in the hospital field, but in all the circumstances the Staff Side is satisfied that hospital staffs will welcome them as a reasonable adjustment to the position as it exists today.

SCOTLAND IN 1953

THE report for 1953 of the Department of Health for Scotland¹ remarks that during the year the new system of remuneration of general practitioners led to a notable increase in the number of doctors practising in partnership, and also contributed to a more even distribution of patients among doctors. At the end of the year there were 2527 principals participating in the service, of whom 1427 (56%) were in partnership, and there were 273 assistants. Corresponding figures for the previous year were 2438, 1285 (53%), and 306.

The gross cost of running Scotland's first health centre, at Sighthill, Edinburgh,² which was built at a cost of £157,000, is £13,000 a year—without provision for redemption of capital cost, for the remuneration of doctors, dentist, and pharmacist, or for the cost of drugs dispensed in the pharmacy. The Exchequer bears £4500 of this, the corporation £6700, and the doctors £1800. A much smaller health centre is being built at Stranraer; but, apart probably from a further experiment on this scale, in a new town, no further health centres are contemplated pending experience of the arrangement for encouraging partnerships and group practice.³

During the year hospitals in some parts of the country found difficulty in obtaining junior staff, particularly house-officers.

"This was partly due to a temporary fall in the number of graduates coming from the Universities of Edinburgh and St. Andrews arising out of the transition of a five-year course of studies in these universities to a six-year course. Even when this phase passes, however, the number of graduates coming from the Scottish Universities each year will be below the high level of the post-war years, and it will not be possible to rely on house officers for the junior staffing of hospitals to quite the same extent as in these years."

New graduates had no difficulty in finding approved posts in which to spend the pre-registration year called for by the Medical Act of 1950. Most new graduates sought such posts in the teaching hospitals, and peripheral hospitals often had difficulty in filling resident posts. Accordingly boards of managements sometimes had to employ senior house-officers instead of house-officers.

During the year the death-rate from respiratory tuberculosis reached a new low level of 23 per 100,000 population—18% below the lowest previously recorded figure of 28 per 100,000 in 1952. Notifications, which had fallen from 167 per 100,000 in 1949 to 144 per 100,000 in 1952, rose slightly to 147 per 100,000.

CONTROL OF DENTAL CARIES

Beginning at the Beginning

ANNE BURGESS
M.B. St. And., L.D.S.

JOHN BURTON
B.A. Camb., M.R.C.S., D.P.H.

DENTAL caries is a painful, harmful, and wasteful disease which is almost entirely preventable. Yet we are not preventing it—presumably because the task seems too difficult. Are there then any comparatively simple and practicable measures which could be relied on at least to modify the present deplorable picture of general dental decay? A review of three reports from Scandinavia suggests that there are.

Lessons from Scandinavia

In Denmark, Norway, Sweden, and Finland a big effort has been made to provide good dental care for children. Recounting his observations as the first Gibbs travelling scholar, James¹ says that in Scandinavia as a whole the ratio of dentist to population is higher than in this country (1:2304 as against 1:3333), and the school dental services are of a high standard.

Routine inspection and treatment are carried out in clinics built for this purpose and forming part of the school buildings. A school of 1000 children will often have two surgeries, comfortable waiting-rooms with toys, books, &c., for the children, and probably other small rooms for sterilisation, radiography, and a rest-room for the staff. In Norway dental hygienists are employed, who chart the mouth, and supervise the children as they brush their teeth before going into the dentist. They attend to scaling and polishing, apply fluoride, and give educational talks.

The acceptance-rate for treatment averages 95%. In Denmark assent is assumed unless parents actively object. In Norway, if a child refuses, free treatment is withheld until he has been made dentally fit at the parents' expense.

The dentist: child ratio is high—Bergen has a figure of 1:560 (which is considered too low by those in charge) and Oslo of 1:800 children, with 57 clinics, of which 3 are mobile. (In Middlesex—one of the best-staffed counties in England—the approved establishment is 1:3000 children, and that is not at present maintained.)

The Scandinavian dental schools have many more applicants than they can accept, and after receiving his free education the dentist must spend two years in the public dental service, or (in Denmark) in a public service or as an assistant in a private practice. Private practice is allowed to many dentists working in the public dental services.

Dental propaganda concentrates on (1) promoting oral hygiene; (2) encouraging good dietetic habits, and discouraging excessive sweet-eating; and (3) maintaining public interest in dental affairs.

The Oslo breakfast—a meal of milk, wholemeal bread, margarine, fresh fruit or raw carrot, meat, fish or cheese—is given to each child on arrival at school. This is considered a valuable part of the routine education for dental health, teaching as it does the proper foods to promote dental health and necessitating adequate chewing to promote self-cleansing of the teeth and development of the jaw muscles and bones.

Posters, leaflets, and pamphlets and periodicals reinforce the importance of oral hygiene, good diet, and the harmful effects of too many sweets. There is much closer coöperation between the dental profession and the press than exists in this country, and items of dental interest are published regularly.

In so far as the aim of the Scandinavian dental-health education is to enable people to keep caries within reasonable bounds and reduce its harmful effects, this education must be regarded as highly effective. Children (and their parents) accept the services of the dentist as a normal part of school life; and such acceptance is,

in the case of the children, encouraged by prizes for good behaviour in the dental chair. Dentists regard the public dental services as rewarding work with recognised prestige. The community as a whole is interested in dental matters, and parents, teachers, and private dental practitioners coöperate well with the public dental services.

But unfortunately the primary object—to prevent or diminish the incidence of caries—has by no means been realised; for the caries-rate in Scandinavian school-children is actually somewhat higher than it is here. Moreover, in a recent investigation in Sweden it was found that the children spent on the average 1s. 5d. per head per day on sweets. James remarked that the children "appeared to be eating or sucking almost throughout their waking hours."

This educational failure is perhaps not surprising when one remembers that before they start school, with its regular dental care, most of the children are 7 years old and their eating habits are already formed. Children are quick to please their parents by learning to like the sweets which are continually presented to them as desirable—as gifts, rewards, bribes, and treats; and once such a habit is established, it is as hard to cure or moderate as any other addiction. Moreover, the very excellence of the school dental service in Scandinavia must make people regard caries as inevitable, especially as emphasis is placed, by rewards and penalties, on a passive acceptance of cure rather than an active personal endeavour to remain caries-free.

Except in Norway, dental supervision and treatment are not given free to the pre-school child, and the fact that a charge, however small, is made, must tend to create an impression in the parents' minds that pre-school dental care is more of a luxury than a necessity.

MOTHER AND CHILD

Toverud,² has shown that preventive measures begun during the mother's pregnancy cause a greater reduction in caries than those begun even in the first year of life. His advice to mothers emphasised the importance of a good calcifying diet and the minimal use of sugar, as sweets or sweet cakes. Education of the mother before the birth guards against the early introduction of the child to the taste of sugar on dummies dipped in sugared water, honey, or rose-hip syrup, or in the "suckable" sweets so often given in the first year of life. In Toverud's "health station" the children and their mothers were also instructed, by a dental hygienist, in cleaning and brushing the teeth.

"SUGAR CLEARANCE"

Claes Lundqvist³ has tried to discover whether the timing and method of consumption of carbohydrate foods affect the incidence of dental caries. Having established that, until sugar is taken by mouth, the saliva is sugar-free, even if there is hyperglycæmia, he measured the time taken for the saliva to become sugar-free after eating sugar in different quantities and forms, and at different times of day. Of customary foods, candy, honey, and sweetened breads had the highest "sugar-clearance time," and normal toothbrushing habits did not prevent exposure of the teeth to a harmful sugar solution for a large part of the day. To induce everyone to brush the teeth immediately after taking any sweets or sweetened foods is out of the question; but Lundqvist found that, after saturation of the oral cavity with sugar, one rinsing with 20 ml. of water rapidly lowered the sugar content in the saliva. He therefore recommends that the mouth should be vigorously rinsed with water (which is then swallowed) immediately after all meals and also immediately after eating anything sweet.

What Might be Done

The exact process by which dental caries is produced is not yet known, but it is a combination of decalcification of the mineral matter and decomposition of the organic matrix of the tooth. Decalcification takes place in an acid medium, such as is created when soluble carbohydrates are available to acidogenic bacteria. The decalcifying solution is kept in contact with the tooth surfaces by any residue of food particles in the mouth.⁴

In this and other countries the incidence of caries was substantially lower during the war and in the years immediately after it, when sweets, sweet cakes, and white bread were scarce or unobtainable.⁵ But this reduction is now being reversed, and the caries-rate is again rising.

In Britain today, then, the situation is that dental caries is on the increase; the dental service to school-children and the priority groups remains grossly inadequate; and the highly refined carbohydrate foods—sweets, cakes, and buns—are increasingly available. This serious state of affairs, and the difficulty of meeting it by traditional means, has directed attention even more urgently to methods used abroad.

Ancillaries.—In New Zealand, where caries is prevalent, the school dental services are operated by dental nurses who, after two years' training, are qualified to do all the routine work—inspections, scalings, simple fillings, and extractions for the pre-school and school children—and also carry out dental-health education. This system has been found to work well.⁶

Other countries have adopted the dental hygienist, whose training lasts one year and who is generally restricted to educational work, and scaling, cleaning, and regular inspection of the teeth. The usefulness of hygienists depends on there being a more or less adequate team of dental surgeons who can delegate the simpler procedures to them. In the absence of enough fully qualified personnel—as in Britain today—the hygienist is unlikely to have much scope.

Fluoridation of Water-supplies.—Fluorine is thought to act by increasing the resistance of the tooth structure rather than by reducing the activity of caries-producing organisms. The U.K. mission which visited the United States and Canada has recommended that controlled investigations of the effect of fluoridation be made in this country⁷; but past experience of preventive measures applied on a national scale (e.g., diphtheria immunisation) suggests that a long time will elapse before the research findings on the efficacy of the fluoridation of water can be implemented.

What then can be done now? Scandinavian experience shows the limitations of even a highly efficient school dental service, and of dental-health education of the public as generally carried out today: existing caries is controlled but its incidence is not reduced. What stands out is the need for dental-health education to be a recognised part of the general health education and supervision of the expectant mother. Stress should be laid on the mother's nutrition—on the advantages of consuming enough protective (and particularly calcifying) foods, and the disadvantages of consuming too much refined carbohydrate. If the child becomes habituated to the taste of sweet substances from the first year of life, later exhortation to reduce the consumption of sweet foods is practically useless. But the taste for sweets is an acquired taste. If a child is not given the usual early training to regard sweet things as "treats," he grows up without any special preference for such things.

Furthermore, mothers should be taught to give the child a drink of water at the end of each meal. Later this can be developed into a more vigorous rinse—but the habit should be begun as early as possible. We believe that a determined effort should be made to spread

this knowledge widely. Money now devoted to the instruction of children and others whose eating and oral hygiene habits, and whose values about dental health, are already formed should be diverted to "educating the educators"—doctors, nurses, health visitors, midwives, the personnel of day nurseries and nursery schools, and teachers in contact with parent-teacher organisations and adolescents in school.

We think it also desirable that the services of a dental auxiliary should be available to mothers and children attending antenatal clinics, infant-welfare centres, day nurseries, and nursery schools. To all children attending the centres, nurseries, or schools, and to those referred by the family doctor, the dental auxiliary would give regular routine inspection, instruction in oral hygiene, and simple treatment where required. Doubtful or difficult cases could be referred to the local-authority dental surgeon or to private practitioners coöperating with the dental service. Even without the evidence about New Zealand dental nurses, our experience in other fields, such as midwifery and nursing, should have convinced us that, in their own restricted fields, ancillaries can achieve greater skill than a general practitioner. Their use in dentistry would release the dental surgeon to practise dental surgery in the fullest sense.

In his report for 1951 the Chief Dental Officer for Middlesex wrote:

"Unfortunately, the nursing and expectant mothers have got out of the habit of visiting the dental clinics, because so many of these have been closed down for long periods. A great deal of re-education will be necessary in order to persuade them of the value of complete dental fitness during the period of gestation and the subsequent nursing period.

"To achieve this re-education it will be necessary to have the coöperation of the medical and nursing staffs who so ably assisted in building up the maternity and child welfare dental services before the National Health Service Act came into force."

This "coöperation in education" is vitally important, and not only for assuring the dental health of the mothers but for preventing a further decline in the dental health of children. The doctors and nurses are ready in the welfare centres to do their part. If the dental members of the team are not forthcoming, then substitutes should be found. In 1921 the *New Zealand Dental Journal* said:

"Public necessity must take precedence over the interests of the individual, or the demands of any dental school, wherever conducted. . . . When the Director of Public Dental Services demands in the near future some 200 assistants to cope with work urgently required, and the Dean of the dental school can promise but a possible 20 or 30, a discrepancy is shown to the disadvantage of the public which cannot be bridged by present methods."

That is still the situation in this country today, and it must be faced realistically.

Tuberculosis in Glasgow

Opening a chest clinic at Belvidere Hospital, Glasgow, on March 26, Commander T. D. Galbraith, M.P., under-secretary of State for Scotland, remarked that since the start of the National Health Service in 1948 more than 1500 additional beds (including 200 in Switzerland) had been provided for Scottish tuberculosis patients. The number of staffed beds—about 5750—was more than three-quarters of the number of new cases last year. "In other words, if the present waiting-lists could be overtaken we would then be able to provide an average stay of over nine months for each newly notified patient even if the present rate of notifications continued." But in Glasgow alone 900 patients were on the waiting-list at the end of last year. New beds could not be brought into commission without more nurses.

"In these circumstances I have been surprised and bitterly disappointed that certain of our Glasgow hospitals have not seen their way to coöperate in a scheme of seconding nurses under training from general hospitals to sanatoria, which has been successfully tried out in the South-Eastern and North-

Eastern Regions in Scotland and in many English cities. These schemes have enabled many more beds to be staffed, and it is not surprising in view of the precautions that are now taken that the health of the nurses taking part has been excellent. It is also significant that the nurses have thoroughly enjoyed the work, have found it a valuable part of their training, and have been proud of the part they have played in the fight against tuberculosis."

By improving the facilities for outpatients, the turn-over in hospitals could be speeded and the best possible attention be given to patients at home. Commander Galbraith accordingly welcomed the plan to build five new chest clinics in Glasgow, of which this was the first.

Deaths in 1953

According to provisional figures issued by the Registrar-General,¹ the death-rate in 1953 for cancer of the lung and bronchus was 343 per million population of England and Wales. In women the rate remained steady (99 per million, compared with 98 in 1952), but among men it rose to 607 per million from 568 in 1952. The death-rates for all forms of cancer were 2165 and 1836 per million in men and in women respectively, compared with 2151 and 1850 in 1952.

The death-rate for respiratory tuberculosis was 179 per million—a decrease of 16% from the previous year. The rate for other forms of tuberculosis was 22 per million (28 in 1952).

1. Registrar-General's Return for the Week ended March 27, 1954. H.M. Stationery Office. Pp. 20. 1s.

The rate for maternal mortality (excluding abortion) was 0.65 per 1000 live and still births, compared with 0.59 in 1952—the lowest ever recorded.

The Widdicombe File

X. THE PAINLESS APPENDIX*

DEAR LAWSON,

We have never met, but I see that you are a King's man, which means that you have been well brought up and have learnt the basic principles of surgery at the feet of my friends John and Cecil and Harold. You have also learnt what is even more important—to accept the teaching of authority as a working hypothesis only, till you have proved it by your own experience.

You ask me whether I have met an appendix abscess that has developed with no abdominal pain whatsoever until it ruptured. I have, and so will you some day; but you will not be misled if you have listened carefully and examined conscientiously.

Pain is due to tension on nerve-endings, and it is therefore nearly always present at some time in an inflammatory lesion—usually in its early stages. The classical signs of inflammation are, as you know, *Rubor, tumor, calor, et dolor*. The pain arises in tension and is usually most marked when the tension is increasing. It is slight if the tension increases only slowly; it diminishes when the tension ceases to increase; and it disappears when the tension is relieved, or the nerves die—that is, when the abscess bursts or the inflammation goes on to gangrene.

The appendix is insensitive to all those mechanical, thermal, and chemical stimuli that cause pain when applied to the skin or the parietal peritoneum. It responds to an increase in tension either in its lumen or in its walls by a viscerosensory response—colicky pain referred to the umbilicus and vomiting. This is merely a midgut reflex common to all parts of the alimentary tract supplied by the superior mesenteric artery and its branches when they are subjected to tension: there is nothing to distinguish early appendicular colic from the colic occasioned by unsuitable food or by an aperient. As soon as the walls become inflamed, the visceral stimulation, and with it the colic and vomiting, cease, and true pain follows only if the inflamed appendix lies in contact with some structure able to appreciate pain. In classical appendicitis the appendix lies in its classical position, somewhere in the right iliac fossa, where the parietal

* This is a copy of Sir Daniel Whiddon's reply to Dr. G. G. Lawson's letter in our issue of March 20.—Ed. L.

peritoneum responds by pain to the contact of any surface that differs from its normal environment of peritoneal surfaces equally smooth.

* * *

May I cite some examples of painless appendicitis I have met?

1. *Pain was absent because the inflammatory process developed only slowly.*—A girl of 22 consulted her doctor one Monday evening because she was feeling unwell. She was due to be married on the Tuesday week. She had been feeling "mouldy" ever since the previous Wednesday, a little mouldier each day, but she had had no pain, vomiting, or disturbance of her normal bowel habit. Her period, which had just ended, was a normal one. The doctor found that her pulse and temperature were normal and her abdominal muscles were not on guard, but she was definitely tender on deep pressure over a well-demarcated area medial to McBurney's point and well above the pelvic brim. On rectal examination no tenderness was found till the uterus was moved by pressing on the cervix.

Though the girl had had no pain, she certainly had a tender appendix. In view of the approaching wedding, I should have been tempted to wait and hope, had the history been a short one; but ten days' malaise meant a slowly progressing infection that could not be expected to subside. The appendix was swollen and a dusky red, and contained thick pus, but the peritoneal reaction had not got beyond a clear effusion. The wedding took place on time.

2. *Pain was absent because the inflammatory process had been aborted by antibiotics.*—A medical student woke up with a sore throat and a temperature the day before his Finals. He gave himself a shot of penicillin, and repeated the dose that evening, and next morning before he went to write his papers. He felt slightly worse that evening, but had no pain and only slight pyrexia. He gave himself an injection of penicillin night and morning for the next eight days till he had been up for his vivas which he succeeded in passing. That evening he felt too ill to celebrate and went to bed early. There, for the first time, he felt a lump in his right iliac fossa. He dressed and sought out the Registrar on duty and asked him to examine him. At operation two hours later he was found to have a gangrenous appendix lying in a small abscess cavity and walled off by omentum.

3. *Pain was absent because the appendix was lying in the pelvis.*—The missed pelvic appendix is seen several times a year in every large general hospital. The patient has felt ill for some hours, and later has complained of central abdominal colic and vomiting. His temperature has been found elevated, perhaps to 101°F, and his pulse has been accelerated, perhaps to 96; but on palpation of the abdomen no tenderness and no guarding have been discovered. A provisional diagnosis of gastro-enteritis has been made, and the patient has been taken off work and sent to bed, where he has been visited twice daily. His temperature has remained elevated, his pulse-rate has risen slowly, and he has started to look ill. He has refused food. Repeated enemas have produced little beyond flatus. He has then started to get diarrhoea, and the diagnosis of gastro-enteritis seems to be confirmed. Then one day the appearance of a lump above Poupart's ligament, or a gush of pus from the rectum, has established the true diagnosis.

The inflamed pelvic appendix is painless because it lies among viscera that have no pain fibres. It is tender when it is palpated, but it can only be palpated from the rectum.

4. *Pain is absent because the patient is not appreciative of pain.*—Just as the same wireless programme differs according to the quality of the set on which it is received, so the same painful stimulus produces quite a different sensation in different cerebral cortices. What is agony to one man is a discomfort barely worth mentioning to another. The old are apt to be either insensitive or uncomplaining; at any rate appendicitis in them is very often met in the guise of an abscess appearing without previous symptoms. The man mentioned in my previous letter was an example of such a clinical picture. Any surgeon of my seniority will recall others. Even when there is pain, the old hate to make a nuisance of themselves. They have had many bellyaches in their time. This is another. If it doesn't go tomorrow, a good "clear-out" will put it right. The dose of "health salts" sets up a peristalsis in coils of gut that have been trying to wall off an abscess, and floods the peritoneal cavity with pus.

* * *

Medicine is an entrancing study because it cannot be reduced to set rules. We can learn the typical picture of any disease, which is compounded of the features of the disease process and the way it affects the form and functions of the organ or system it attacks, and of the modifications imposed on that process by the age, sex, and general health of the victim. We must learn the typical picture, but we shall be constantly modifying and enlarging it as we meet further instances of the disease in which some of the familiar features are missing or new ones are added, and by experience we shall learn wisdom.

When I was a student, the Registrar who tried to teach me medicine recounted the story of a conscientious student, who recorded his daily experiences in a notebook. One of his patients suffering from typhoid was caught by the Sister eating the last of two dozen oysters smuggled in by his wife. To everyone's astonishment he improved rapidly. The student made an entry "Oysters are good for typhoid." Shortly afterwards he went on a holiday to Paris with a friend. The friend contracted typhoid, and, remembering the former case, the student bought him two dozen oysters. The friend ate them and died. The student turned back to his former entry and added a footnote—"Oysters are good for typhoid, but not in Paris." Had he lived long enough, seen enough cases of typhoid, observed them as carefully and recorded the results of his observations, this student would have died the wisest typhoidologist in Europe.

If you ever travel to the West Country I hope you will look me up.

Yours sincerely,
DANIEL WEIDON.

In England Now

A Running Commentary by Peripatetic Correspondents

AN annual report should be stirring, amusing, telling, revealing, and written with fire—but briefly. Turning its readers from the revulsion which they naturally experience at the sight of it, it should rouse them to passionate enthusiasm for the Cause, whatever that happens to be. Of course some readers are easier game than others: I am easy game myself; partisanship comes so naturally to me that I sometimes think I have Irish blood. But even a born partisan can be choked off so completely by a stodgy report that you can hardly tell him from a Scot.

As a constant reader—perhaps the only constant reader?—of this type of literature, I am in a position to offer a few tips on flavour. First, I can fully recommend the reports of the Muffled Foundation: they have the right air of being breathless (if not silent) on a peak in Darien, with a sea of new things to be done lying straight before them. The Effingham League for Senile Reform also do well, though they are inclined to be almost too moving. The Board of Tightlip err in the opposite direction, mumbling out a quantity of figures; and even when these bear a favourable interpretation the report contrives to sound a decayed and melancholy note. The Royal Association for Psychic Toleration (R.A.P.T.) is spirited enough, but has a told-to-the-children flavour not acceptable to all. Presumably a pen lies behind the printed page of every annual report, and a person behind the pen. Perhaps it has not struck this ambiguous character that he has a reader? Should I offer to publish for his benefit an Annual Report on Annual Reports, this being the first? But no: in the character of Constant Reader, I find my remarks rouse no answering spark in myself—only a Caledonian-type repugnance.

* * *

Once upon a time there were very few maternity hospitals and all the mothers had their babies at home. Some of the bad cases died, and everybody was very sorry. So they built lots and lots of new maternity hospitals to take the bad cases, and not so many died, and everybody was happy. It was such fun for the mothers to go to hospital to have their babies that it soon became hard to find a bed for the bad cases, but all the mothers explained very loudly why their own homes should not be upset by the new babies.

And once upon a time, a bit later than the last time, there were very few geriatric units, and all the grandmothers died at home in the loving care of their children, and everybody was happy. So someone built lots and lots of geriatric units and homes for the aged sick, and the grandmas died well away from their children, and no-one could care less. It was such fun to get rid of the grandparents that it soon became hard to find a bed for the bad cases, but all the children explained very loudly why their own homes should not be upset by the grandmothers.

It is so much nicer to sit right in front of the television, and have plenty of room on the kitchen table to fill in your football pools, and be able to go to the cinema whenever you want. After all, you stamp your cards every week so it's only right that someone else should have the bother of looking after baby and grandma. St. Augustine? Never heard of him.

* * *

The arrival of spring has ended the armistice imposed by "winter and rough weather"; the campaign has opened, and the attackers have taken the field in force with all the latest weapons. With his right hand on the hilt of his drawn sword, and his left clasping a telescope to his martial breast, Lieut.-General Sir James Outram, the "Bayard of India," surveys the battle from his panoplied pedestal in the Victoria Embankment gardens. Which side is he backing? The gardeners or the leather-jackets? And what a strange thing it is that these larvae of daddy-long-legs should thrive under the very beaks of thousands of roosting starlings, whose favourite food they are. Do the birds, like some human beings, despise what is close at hand and lust after the exotic and far away?

* * *

Letters to the Editor

My wife lately sent an article to one of the shiny magazines. She wrote as a housewife and mother of three children, and the article seemed to me reasonably terse, human, interesting, and practical; but as it described acquaintances, we thought that if accepted it would have to be signed with a pseudonym.

We attacked this problem lightheartedly enough. Perhaps a name from Jane Austen—Emma Woodhouse? No. Emma wouldn't write this. Elizabeth Bennet might, but the name was somehow inappropriate. So we decided to invent an elegant, friendly, well-balanced name that would suggest common sense and charm. My first suggestion of Carol Underwood was rejected out of hand, a judgment which, now, a week later, I think was fair enough. I then suggested Elspeth or Janet Something, but my wife declined to pose as a Scot. We wanted a pleasant-sounding name with a human touch—yet not too down-to-earth, like Martha Butt; nor too exotic, like Berenice, Hildegarde, Carmen, or Alys; nor too literary, like Imogen or Miranda; still less too Hollywood, like Gloria or Marlene. Then what about a sound, non-committal, correct name like Mary or Ann? The problem then would be to find a suitable surname to go with it. My wife turned down several of my suggestions on the ground that she "knew them at school." Jennifer and Penelope seemed a little young, and I was obdurate about Camilla, which my dictionary says means "an attendant at a sacrifice."

This week's *Lancet* lying on the table suggested anagrams, and we worked out Thea Clent, Tena Chelt, and the sinister-sounding Lethe Cant before we sadly gave up. We were still discussing the matter when the article returned to us with the Editor's regrets.

* * *

The undertaker who preferred to have his operation in the hospital where the mortuary was not so damp (this column last week) reminds me of a post-mortem-room attendant at my hospital many years ago, who needed surgery for a severe disease. Asked by the R.M.O. to choose his surgeon, he named Mr. A. When asked why, he replied "because I have seen more of his work than of the others'."

* * *

"Pay no heed to these marks," she said when I was examining her offspring at the clinic. "It's what the doctor calls that popular dirty area."

* * *

The modern operating-table is a beautiful engineering job, enamelled and plated, with lots of handles and a fine miniature railway to which to fasten the dinglumdanglums. But it has two serious defects.

The hinges—or breaks as they are often humorously titled—divide the table symmetrically, without apparent regard for the distribution of the main bends in the human frame. Thus, the central break—for kidneys and gall-bladders—comes where a patient, lying comfortably, keeps his pelvis. Move the body to the break and the feet project from the end of the table while the other end of the table compresses the anaesthetist's chest. Equally, the two minor breaks occur below the knee and about the middle of the scapula. To cope with this we are designing an infinitely bendable table in polyvinyl plastic.

The other defect is more subtle. Tables can be moved skyward or cellarward, usually by footpump, so that the work can be accommodated to the eye level of the surgeon. But our Mr. Short needs a low table, which means that his assistant Dr. Long risks his discs and his cortisone and develops a postural kyphosis, threatening soon to become fixed. Mr. Short will not operate on a box, which might allow a high table and relieve Dr. Long; he is afraid he will fall off. We have tried tipping the table sideways, but surgeons obstinately remain vertical. However, we feel we have the answer at last. In coöperation with the engineer we have devised a neat, fully adjustable, and portable hole-in-the-floor, with which we are confident we shall be able to make Dr. Long comfortable.

* * *

Treating patients is like playing the violin. You can write books on the general principles, but it takes talent to give a performance, and outstanding talent to give an outstanding performance.

LABELS FOR INTRAVENOUS FLUIDS

SIR,—The importance of precision in intravenous therapy is now widely recognised, not only in the volume of fluid administered but also in its crystalloid composition. This precision is hindered by the bewildering variety of labels which manufacturing chemists use to designate their products. Not only are the colours of the labels and the style of printing unstandardised, but different words are used by different firms to describe identical solutions. In particular, solutions of normal saline in 5% dextrose may be labelled in such a way that only careful scrutiny shows that there is salt in the bottle. It is therefore not surprising that from time to time mistakes are made because a label has been misread.

For many years the possibility of this sort of mistake in anaesthetic practice has been recognised and met by a uniform system of marking cylinders of anaesthetic gases. Admittedly the dangers of administering the wrong bottle of fluid intravenously are not so great or acute as those of giving the wrong anaesthetic; nevertheless, dangers do exist and every effort should be made to prevent them. It would be a distinct advance if the manufacturing chemists could agree to label their solutions for intravenous infusion in a standard fashion, and the use of different coloured labels for the different fluids would be a great help to clinicians in the wards.

Middlesex Hospital,
London, W.1.

IDENTIFICATION OF DRUGS

SIR,—Every doctor has been faced with the difficult task of identifying tablets or capsules for patients. Drugs of widely different pharmacological action are made up in similar form. Conversely, pharmaceutical firms market the same drug in tablets of quite different shape, size, and colour. The problem takes on a more serious and urgent nature when the casualty officer is faced with a comatose patient and some pills are found in the patient's possession. Their rapid identification might enable him to give the correct antidote without delay. Moreover, many patients may swallow dangerous tablets because they confuse them with less dangerous compounds of similar appearance.

My attention was again drawn to the problem when some tablets, probably cortisone, were found in the possession of a patient who had died of coronary occlusion; they could not be definitely identified on sight, even by the staff of the regional centre from whom she had been receiving this drug.

I suggest that all tablets containing drugs on the Dangerous Drugs list should bear a standard imprinted mark. Secondly, tablets in this class should also be stamped with a number or letter code so that by reference to a list supplied to all hospitals, doctors, and pharmacists, it would be possible to identify the dangerous drug in the tablet. The trade-name could be imprinted on the reverse side. I also feel that all capsules containing dangerous drugs should conform to a uniform colour key.

I am writing to the Association of Pharmaceutical Industries to seek their advice and suggestions, and I hope that the coöperation and support of the pharmaceutical firms will be gained in this matter. It would be one of great importance as a safeguard both to the general public and to certain patients in particular.

Farnborough Hospital,
Kent.

M. B. KING.

HOSPITAL, DOCTOR, AND PATIENT

SIR,—While I appreciate how difficult it would be for consultants to make themselves regularly available to visiting relatives, I still think that the letter signed "Parent" in your issue of April 3 raises an important question, to whose consideration I should like to contribute two observations.

Firstly, I have found it necessary to expand my visiting-list by continuing to call on my patients while they are in hospital and, on the same day, on their families. This is the only way in which they can get any information and therefore the only way to prevent the spread of alarm and despondency.

Secondly, at a postgraduate course for G.P.s which I attended recently we were informed, as a body, that patients regarded their family doctor with undue trust and unmerited esteem.

Could these observations be connected, do you think?

York.

F. CHARLOTTE NAISH.

SIR,—For quite a long time we have read the complaint that patients in hospital are not told what is the matter, or what is to be done. These complaints have appeared in the popular press; in the reports of judgments delivered in the High Court; and now in your own columns. This seems to raise a question of serious import. In my own case, I try in an emergency to make the patient understand what is going on; and in rare cases (for example, if total removal of the larynx is proposed) I write to the patient's doctor, and to the patient, and then ask him to come for a special interview to ensure he knows all that is implied in the procedure.

But in nineteen cases out of twenty I say (in the out-patient department) "I will write to your doctor: go and talk it over with him." And when a patient is discharged from the wards, the same advice is given. We try to ensure that the family doctor is kept informed of the diagnosis, the proposed line of treatment, our findings, and our recommendations for aftercare. But I do rely on the *family doctor* to tell his patient as much as he thinks suitable. And I feel sure that this is the tradition of many years. I ask you, Sir, to guide us as to whether this old—and, in my opinion, essential—tradition must be sacrificed at the bidding of laymen, who have often little insight into the patients' best interests.

Bristol.

E. WATSON-WILLIAMS.

RESPONSIBILITY IN HOSPITAL

SIR,—The letter from Dr. Hamilton (March 27) claiming that the doctor should bear all the consequences of his professional decisions is pertinent and timely. Unfortunately his conclusion depends on the assumption that his professional decisions can always be made in isolation, and this is no longer always true.

A doctor working in a hospital makes many decisions which are modified by the prevailing circumstances in that hospital. If the hospital is understaffed or otherwise inadequate he may have to make what he knows are bad decisions, dictated by expediency. He may, for example, have to give blood to a patient under conditions which involve rejecting the advice of a recent circular on blood-transfusion in at least three separate and important places. If an accident results, such as the circular attempted to prevent, should he be blamed for flouting the advice? It appears rather unjust, to say the least, that he should be held entirely to blame for a professional "mistake" which was forced on him by the inadequacy of the organisation in which he works. His mistake is professional but the causes are administrative, and surely this should be fully recognised before any question of liability is considered. If authority decides that a

hospital is to undertake responsibilities for which it is inadequate, then that authority should accept the consequences of that inadequacy, professional or administrative.

Woolton, Liverpool.

H. E. VICKERS.

THE HOSPITAL MAKES FRIENDS

SIR,—Dr. Hardcastle complained in his letter of March 20 that the reports that he receives from hospital seldom contain any useful information. I am sure that all of us who have worked in general practice will agree that hospital reports are sometimes of no value, and I am equally sure that those of us who work as hospital registrars will say that the general practitioner is usually to blame. It is really a remarkable circumstance that a well-educated man is prepared to send to another a letter which is often devoid of syntax, may contain no words given in the Oxford Dictionary, and is almost always too short to convey any idea of the reason why it was written. Two examples, taken from letters brought to last week's clinic, ran as follows: "Patient's name and address. Recom. for investn. chest condition. Signature"; "Patient's name. † dust. Yrs. Signature." Even the rather longer letter may be grossly misleading, and I recently received one in which the practitioner failed to mention that the patient had been attending the chest clinic for two months and was to be admitted to a sanatorium in six days' time for treatment of a pleural effusion. Some practitioners' letters are so misleading that I know of one senior physician who tells the students that he never reads the doctor's letter until after the patient has gone!

This is, of course, an absurd situation and may be the cause of some of the "useless" letters written to practitioners. Two such letters ran as follows: "I agree with your diagnosis and think the patient should be given radiotherapy"; "X-ray shows evidence of back pressure on the pulmonary circulation but no other abnormality." No doubt every practitioner has his own collection of prizewinning "useless" reports.

These are amusing stories, but this is a serious problem and I feel convinced that the practitioner does not get a "useful" reply because he does not make it clear what information he requires. Consultants are possibly not, but registrars certainly are, just as stupid as the rest of mankind and cannot be expected to divine the practitioner's wishes. The type of letter that I have quoted, which accounts for perhaps a quarter of those received at hospital, is quite obviously worthless when transferred to other professions. Who would write to the travel agent "† Blackpool" or to the solicitor "Recom. for trust fund" †? If the practitioner wishes to know the blood-potassium level or the changes in the electro-encephalogram he must say so, and if he does not wish to know them he must not say merely "Please see and advise."

The practitioner is always in a position to give very valuable information about the patient's home and habits, but it is extremely uncommon for him to do so and a flood of social workers has to be employed to duplicate his work (and to do it rather less well). Having recently left general practice, I realise how much is lost when one does not know the patient's social background, and I have the greatest respect for the G.P.'s special knowledge of it. So far my efforts to benefit from this knowledge have met with no success whatever, and I have never received any reply to the various questions that I have asked numerous different G.P.s.

It may be claimed that the burden of work on the G.P. is too heavy for him to find time to write fully and clearly, but I cannot believe that the burden is in any way lightened by the writing and receiving of useless letters. I have tried talking to the doctor on the telephone, but found that he was unable to give any information

"off-hand," and I have issued three separate invitations to another doctor to call at any time that is convenient to discuss a particularly difficult problem. Once again I have had no reply.

In spite of all this, I believe that the general practitioner is the most important member of the health service, and I most earnestly wish to see more coöperation between practitioner and hospital; but I can assure Dr. Hardcastle that the organisation of such coöperation is weary uphill work.

REGISTRAR IN TEACHING HOSPITAL.

CONTROLLED HYPOTENSION WITH ARFONAD

SIR,—The recent reports of the use of 'Arfonad' have been very interesting. We believe that any hypotensive technique should be used only when it is considered essential for the success of a particular operation. Our present experience with arfonad is, therefore, necessarily small; we have used it in 21 aural fenestrations and 5 craniotomies. We would, however, like to record that our findings are almost identical with those already published in larger series.

The anæsthetic technique recently described¹ for neuro-surgical operations has been used in every case, and it is essential, if cozing is to be avoided even when arterial pressure is low, to ensure a perfect airway, spontaneous respiration, and correct posture. The tachycardia that may follow the injection of gallamine triethiodide should preclude this drug in any hypotensive operation. The standard drip chamber has been used with a pendulum² and fine-adjustment regulator.³ This has allowed satisfactory control of dosage of an 0.1% solution. The ages of the patients in this series have ranged from fifteen to sixty-five years, and the average dosage has been at the rate of 2.3 mg. per minute.

We have been particularly impressed by the control during the induction of hypotension with this drug. The "pressure floor," mentioned by Dr. Scurr and Dr. Wyman (Feb. 13), and the individual variation in dosage required have been confirmed. Difficulty has been experienced in lowering the pressure in 4 cases, but even with a systolic pressure of between 80 and 100 mm. Hg, bleeding has not been troublesome. It seems that the lowering of the pulse-pressure to between 10 and 15 mm. Hg is more important in stopping bleeding than an absolute reduction of blood-pressure. In 4 long cases it was found that, after about 100 minutes, it was suddenly necessary to double the drip-rate to maintain the previously established blood-pressure. This change did not appear to be related to any change in the anæsthetic or any operative procedure. Like others, we have found procaine amide of value in reducing tachycardia. We would also stress the importance of replacing any blood that may be lost; if this is not done, difficulty will be experienced in restoring the blood-pressure to normal.

Cessation of administration has been followed by an immediate rise in blood-pressure, but it has often taken over 30 minutes to return to normal. In the neurosurgical cases, the systolic pressure has been allowed to rise to 90 or 100 mm. Hg before replacement of the bone flap, so that the surgeon could stop any bleeding. The postoperative condition of the patients has been excellent; there have been no cases of prolonged hypotension and no complications attributable to the anæsthetic.

The results published so far suggest that arfonad is a valuable drug, provided it is used with care and discrimination.

PREVENTION OF AIRBORNE INFECTION

SIR,—In your issue of March 6, Mr. Baker claims that a continuous-flow aerosol of hexylresorcinol might be used instead of ventilation to control the numbers of airborne bacteria in operating-theatres and dressing-stations, although he admits that no reports of its use for this purpose are available to justify his claims. We have recently completed analyses of an investigation of the use in clerical offices of hexylresorcinol vaporised from the thermal generators described by Mr. Baker. In this situation, no reduction was detectable in the bacterial counts in the air with the vaporisers working normally; and even when the vapour concentration was increased sixfold, and produced some throat irritation among the occupants of the room, the rate of kill of bacteria sprayed from the mouth was equivalent to no more than 6 air changes per hour.

The results of these investigations will be published in full elsewhere.

BLOOD-UREA LEVELS OF WEST AFRICANS IN LONDON

SIR,—The observation of Phillips and Kenney¹ that the plasma-urea level in a small sample of West Africans was as low as 13.9 mg. per 100 ml. prompted us to compare a group of West African students in London with a series of English males of similar age-distribution. Twelve of the Africans were from the Gold Coast and the rest from Southern Nigeria; the Europeans were University staff, students, and technicians.

The urea was estimated on oxalated whole blood, freshly drawn by venepuncture, by Conway's method,² using urease Dunning tablets as the enzyme preparation. All estimations were performed in duplicate; samples from both Africans and Europeans were run in each batch of determinations together with a standard urea solution. We were subsequently able to examine a small series of serum specimens from blood obtained by venepuncture from African technicians at the University College, Ibadan, Nigeria, and sent by air to London in vacuum ampoules packed with ice. We are indebted to Mr. J. P. Garlick for this material and for certain information about the subjects. The data are summarised in the accompanying table.

Sample	No.	Sex	Age (years)		Mean blood-urea (mg. per 100 ml.)
			Mean	Range	
English	18	M	28.2	20-42	27.97 ± 1.32
London Africans ..	21	M	26.0*	21-29	24.78 ± 0.84
Ibadan Africans ..	13	{ 12M 1F	::	::	} 16.56 ± 1.57

* Based on 18 subjects.

The mean value for the London Africans compared with the English gives a value of $t = 2.19$ for d.f. 37, which is just significant at 5.0%, so that there is some evidence that, even on a European diet, the African blood-urea level is slightly low. The African subjects had been in England for a period ranging from 11 days to 7 years (mean 2 1/4 years). Plotting the urea level against length of residence in England suggested no obvious relation between the two, but the sample is small and includes very few recently arrived subjects. The mean blood-urea level of the London Africans compared with that of the Ibadan Africans gives a highly significant difference ($t = 5.38$ d.f. 32, $P < 0.0001$). When blank determinations were performed on these sera no evidence of prior decomposition of urea to ammonia was found.

Our results tend to confirm Phillips and Kenney's observation that the blood-urea level is low in Africans of intermediate economic status living on a native diet

1. Phillips, P. G., Kenney, R. A. *Lancet*, 1952, ii, 1230.
2. Conway, E. J. *Microdiffusion Analysis and Volumetric Error*. London, 1947.

in their own country. On questioning 11 of the Ibadan subjects, they all stated that they ate meat daily, and most of them also took beans several days a week and some of them eggs and milk occasionally; these were the only important sources of protein in their diet. We may conclude tentatively that their diet was probably not severely deficient in protein, but is likely to have been lower in this respect than the diet of our English subjects and African subjects in London. Whether the higher blood-urea level in the London Africans indicates that the urea level can rise to near European levels on European diet, or whether African students represent a sample whose urea was already at this level in their own country, the present data cannot decide. It is certainly by no means safe to conclude, without further investigation, that African students in London have enjoyed noticeably better dietetic and general medical conditions in their own country than have the group of Africans resident in Nigeria whose blood-urea has been examined. It would be of interest to examine the blood-urea levels, and perhaps other biochemical variables, in the same individuals both in West Africa and in England after varying periods of residence. It may be noted that, as Barnicot and Wolffson³ showed, the daily 17-ketosteroid output is definitely low in West African students in London, and perhaps not very different from the output in African labourers in Nigeria. The present results serve to emphasise, however, that a low blood-urea level does not necessarily occur in all groups of West Africans, and can, under certain circumstances, be close to the normal values accepted for European subjects.

THE COST OF PHARMACEUTICAL RESEARCH

SIR,—Your annotation of March 27 on the memorandum submitted to the Guillebaud Committee by the Scottish Committee of the British Medical Association concludes with a reference to the remarks, made in the final paragraph of the memorandum, concerning the N.H.S. drug bill and pharmaceutical exports and research. It is quite true that part of the cost of proprietary preparations "relates to research undertaken by the firms which produce them"; but surely the research component of overhead costs is a proper charge on the purchaser whether this be the State or a private concern? Indeed, it seems not only just but also highly desirable that the State, as the principal purchaser of prescription drugs in this country, should contribute towards the research expenditure from which the community derives so much benefit.

The suggestion in the Scottish memorandum that the N.H.S. may be subsidising pharmaceutical export trade is unrealistic, since the "N.H.S. trade" and the export trade are complementary—each benefiting from the existence of the other. The prices charged for prescription proprietaries in this country and to customers overseas are about the same, after allowing for the difference in distribution costs, and consequently the question of "subsidy" does not arise. If, however, any financial impediment were to be placed upon the research carried on by the pharmaceutical industry it would become impossible to maintain its export trade at the present high level (about £30 million a year) since it is largely upon the development of new and improved drugs that success in export markets depends. There is also the danger that a slackening of research effort in this country would tend to make the medical profession more and more dependent upon manufacturers overseas for essential drugs.

3. Barnicot, N. A., Wolffson, D. *Lancet*, 1952, 1, 893.

In such circumstances the probability is that the N.H.S. drug bill would soar well beyond its present figure, and, incidentally, the country's balance of payments would also suffer.

Secretary, Association of
British Pharmaceutical Industry.

SEXING SKIN

SIR.—There are indications that the skin-biopsy test of chromosomal sex¹ is being used in cases of hermaphroditism in various centres.² These studies will contribute to the theoretical background of errors of sex development in man; and the method is also of practical value to the clinician. But the limitations of the test must be appreciated and a word of caution may be appropriate.

The principal value of the skin-biopsy test of chromosomal sex in practice is in the differential diagnosis of the two main groups of hermaphrodites, when the clinical examination, short of laparotomy, is equivocal.³ These groups are the female pseudohermaphrodites caused by hyperplasia of the foetal adrenal cortex, and male pseudohermaphrodites. The congenital adrogenital patients have typical female-type epidermal nuclei; cortisone, when administered early, aids in permitting subsequent development along female lines. All male pseudohermaphrodites whom we have had the opportunity of studying to date have typical male-type epidermal nuclei. The latter observation could not have been predicted with certainty and has been rather disappointing, since a proportion of male pseudohermaphrodites have pronounced female characteristics, anatomically and psychosexually. For the male pseudohermaphrodite group, the decision as to whether the patient should be treated as a male or a female must be made on the basis of all available data, and should not be influenced unduly by the male-type nuclei and the inference that the patient bears the male XY sex-chromosome complex.

MURRAY L. BARR.

DIRECT INGUINAL HERNIA

SIR.—Mr. Brown's letter in your issue of Jan. 23 prompts me to reply. As coincidence would have it, I operated on a girl with a direct inguinal hernia on the morning of Feb. 18, and this issue of *The Lancet* arrived by mail plane that same afternoon.

Although I know that this is a rare condition, I do not understand its complete significance and I hope there will be authoritative replies to Mr. Brown's letter.

Using such references as are to hand in an isolated place like this, where mails are uncertain all the year round and where one does not see another doctor for months on end, I have put together the details of this case.

A normal healthy white girl, aged 17, arrived here by komatik on Feb. 12. She was complaining of a fairly large and painful swelling of the right groin. She had had a smaller painless swelling here for as long as she could remember, but two weeks previously she noticed this swelling had become twice its usual size, and was painful with undue exertion. The lump had never been completely reducible. There was no particular time when the increase in size was noticed.

She had a right inguinal hernia, the lump measuring about 4 cm. by 2 cm. It was not reducible partly because, it was assumed, the hernia was indirect. It was concluded that contents of the hernia were omentum, and that it was potentially dangerous. The left side appeared normal. Arrangements were made for admission to this hospital.

1. Moore, K. L., Graham, M. A., Barr, M. L. *Surg. Gynec. Obstet.* 1953, 96, 641.

2. Hunter, W. F., Lennox, B., Pearson, M. G. *Lancet*, Feb. 13, 1954, p. 372.

3. Barr, M. L. *Anat. Rec.* 1954, 118, 280.

At operation, the hernial sac was found to be very thin, covered with fat and adherent to surrounding structures, the fundus being adherent to the round ligament. Contents were omentum. It conformed in type to the funicular variety of direct inguinal hernia.¹ The sac wall narrowed to a well-defined and thickened neck, and proximal to this was a "secondary" sac, also adherent to a thin transversalis fascia. There was a gap of 3 or 4 cm. between the conjoint tendon and the inguinal ligament. This may have been unusually wide owing to the muscular relaxation with spinal anaesthesia, but was apparently a congenital widening.²

After ligation and excision of the sac, and amputation of the round ligament, repair was effected by the Bassini method. This seems doomed to failure when used to repair a direct hernia in the male, but may be successful in this case.

Grenfell Labrador Medical Mission, JOHN S. WHITTAKER.
Cartwright, Labrador.

there will be as many babies with weights below this figure as above it. The table shows, however, that over two-thirds of the babies with third fontanelles, whether mongol or non-mongol, fall into the lower half of this distribution curve. It is also interesting that the one mongol who did not have a third fontanelle weighed over 9 lb. at birth. In this series, third fontanelles were often associated with delayed closure of the posterior fontanelle and sometimes a widely separated sagittal suture. I might add that 2 babies seen recently with spina bifida and hydrocephalus (not included in the series) had poorly ossified skulls, and in each case the largest skull defect corresponded in position to a third fontanelle.

King's College Hospital, London, S.E.5.

R. J. K. BROWN.

THE THIRD FONTANELLE

SIR.—While making routine examinations of babies at a postnatal clinic I have tried to assess the frequency of the third fontanelle in non-mongol babies. Now Dr. Hoyle and Dr. White Franklin have published some statistics on this subject in your issue of Feb. 27, and I should like to add my own observations, for they provide more figures on a subject which has hitherto received little attention.

In 1500 non-mongol babies, all aged six weeks or less, a third fontanelle was found in 45 (3%). This figure is lower than Hoyle and Franklin's 4.3% for types 1 and 2 together, but higher than their figure for type 1 alone (1.8%). In my series I have included only those babies in whom the sign could be easily demonstrated to students and midwives, so that most of them would correspond to type 1 (fontanelle occupying an area of 1 sq. cm. or more), but undeniably some fontanelles of type 2 may have been included. However, most of the babies were four to six weeks old when examined, by which time some third fontanelles might have closed.

During the same period I have examined 12 mongols of comparable age (7 at the postnatal clinic and 5 elsewhere): 11 of these had third fontanelles and in only 1 was the sign absent. Incidentally, I agree with Dr. Carter and Dr. MacCarthy (March 6); I have been taught to speak of the third fontanelle in mongols as "Lightwood's sign."

Although there is little doubt that the sign is considerably commoner in mongols, it is, as we have seen, by no means confined to them. I believe it is misleading to regard it as a sign of mongolism. To me it implies poor ossification of the skull—a finding not unlikely in the mongol, but also to be expected in some babies of low birth-weight, especially if premature.

In the accompanying table I have related my own figures to birth-weights.

Birth-weight	No. of babies with third fontanelles	
	Non-mongols	Mongols
Less than 5 lb.	2	5
5-6 lb.	6	1
6-7 lb.	23	2
7-8 lb.	11	2
8-9 lb.	2	1
Over 9 lb.	1	0
Total	45	11

Anderson et al.³ have shown that birth-weights follow very closely the pattern of a normal distribution curve having a mean of about 7 lb.—i.e., in any large series

THE BIBLE AND MODERN MEDICINE

SIR.—Your review (March 27) of Professor Rendle Short's book refers to the diagnostic problem of Job's ravaging skin disease. The tempo of the drama seems scarcely to match the rapid kill-or-cure course of smallpox. A fascinating alternative clue is offered by recently published cases of psychosomatic or anxiety-induced dermatitis. If we accept that a scrupulous mind, brooding over injustice and the sense of being wronged by authority, may erupt in a generalised eczema, Job's clinical problem is curiously integrated: the Enemy attacks him in the second round, not by an unrelated physical disease, but through Job's very perplexity over undeserved outward disaster to his fortunes and family in the first round. Job's limited understanding can but blame this upon the Almighty, through a faulty correlation in his philosophy between devoutness of religion and material prosperity. Once Job's skin breaks down, the vicious circle is intensified through toxæmia and weariness.

There are, in the Old Testament case-record, corroborative details pointing to an anxiety state: insomnia and terrifying dreams (vii, 4, 14), dread (ix, 28; xiii, 21), shuddering (xxi, 6), and mental confusion in controversy, yet with insight (vi, 3, 26). Besides which, Job loses the moral support of his wife, who counsels merciful suicide.

CEDRIC C. HARVEY.

CHLOROQUINE IN LUPUS ERYTHEMATOSUS

SIR.—The results of treatment with chloroquine in eight cases of lupus erythematosus may be worth recording. Page¹ reported a good response to mepacrine in this condition. Chloroquine may be more active than mepacrine and does not produce yellow staining of the skin, so its trial seemed justified.

In one patient discoid lesions cleared completely after 13 weeks' treatment with 0.3 g. of chloroquine weekly. This dosage was continued for a further 8 weeks and the patient remained well when reviewed 3 months after treatment had ceased.

In another patient the lesions regressed after 10 weeks' treatment (0.6 g. weekly), but recurred 2 months later and did not respond to doses of 1.05 g. weekly for 10 weeks, after which treatment was discontinued because of anorexia.

In a third patient, treated for 7 months, discoid lesions regressed 13 weeks after dosage had been increased to 0.9 g. weekly. Treatment was discontinued because of anorexia. The eruption recurred 4 weeks later and the patient complained of deafness, tinnitus, and vertigo. She could not hear the conversational voice at a distance of more than 2 ft. from either ear; and tuning-fork tests indicated bilateral nerve deafness. An audiograph revealed uniform loss of air and bone conduction, averaging 25 decibels up to 2048 double vibrations per second, and in the higher frequencies the mean loss was 40 decibels. The result of caloric testing by the Hallpike method was within normal limits. 8 months later an audiograph showed no change and the nerve deafness seems likely to be permanent.

1. Page, F. P. Lancet, 1951, ii, 755.

The remaining five patients showed no improvement. One developed a light-sensitisation eruption during the 8th month, and anorexia and generalised urticaria in the 12th month, of treatment with doses varying from 0.3 g. weekly for 13 weeks to a maximum of 1.8 g. weekly for 7 weeks. A second patient developed additional discoid lesions during the 13th month of treatment with doses varying from 0.3 g. weekly for 8 weeks to a maximum of 0.9 g. weekly for 23 weeks. At this time he complained of dimness of vision, but no optic atrophy was present and the visual fields were normal. Three patients who received 3.0 g. in 4 weeks, 3.6 g. in 12 weeks, and 3.6 g. in 8 weeks respectively, showed no improvement.

When administered over long periods in greater dosage than is normally used for suppression of malaria, chloroquine may produce side-effects.²⁻⁴ Toxic effects occurred in our series, and results were so poor that we considered further trial of chloroquine in lupus erythematosus unwarranted.

SEX AND SOCIETY

SIR,—I was surprised to read in your issue of April 3 (p. 737) that the article by Dr. Learoyd in the April issue of the *Practitioner* lacked objectivity. To my mind, it was an admirable article from the point of view of the general practitioner, who may from time to time be consulted by parents on the subject of homosexuality. I agree with Dr. Learoyd that the view expressed by Sir Frank Fletcher (a famous headmaster of a famous public school) in his book *After Many Days* is indeed a model for the treatment of homosexuality, at any rate during the years of adolescence.

Chelford, Cheshire.

E. S. EVANS.

ACUTE LYMPHOCYTOSIS AND EOSINOPHILIA

SIR,—Smith⁵ introduced the term "acute infectious lymphocytosis" to represent a self-limited entity of unknown cause affecting mainly children up to 10 years of age. There are few abnormal symptoms, and therefore the condition often escapes attention. The only constant abnormal finding is the large number of small normal lymphocytes—sometimes as many as 90,000 per c.mm. The number of lymphocytes drops gradually to normal in 2-7 weeks. The condition is mainly sporadic, but occasional epidemics have been described.⁶⁻⁸ Smith believes, therefore, that this is an infectious and contagious disease.⁹

Several authors have mentioned that there is also absolute eosinophilia.^{7 8 10 11} In four sporadic cases observed by us during the last year we found that the increase in the number of the eosinophils was at least as pronounced as the increase in lymphocytes, and in one (case 5) the eosinophilia was proportionately greater than the lymphocytosis. The findings were:

Case	Total white cells per c.mm.	Lymphocytes per c.mm.	Eosinophils per c.mm.
1 ..	81,000	70,000	4860
2 ..	60,000	49,200	3600
3 ..	75,000	66,000	3750
4 ..	58,000	50,000	2900
5 ..	48,000	31,200	8640

SELF-HELP AND NUTRITION

SIR,—The article by Dr. Cicely Williams (Feb. 13) reveals many gaps in our knowledge of nutrition in "underdeveloped" countries. The science of nutrition must be founded on economic, nutritional, dietetic, and social surveys; and more knowledge of foodstuffs is needed than is found in analytical tables. Many surveys have been made in the countries of South-east Asia: and these show that malnutrition is mainly found among the poverty-stricken, which may be largely due to pressure of population.

The food taboos and superstitions and the ignorance existing in some countries attract attention by their strangeness, so that their effect in causing malnutrition is often exaggerated. Many years ago, when I began nutrition surveys in Ceylon, I was told that in certain districts all the people were good Buddhists who would not eat anything which had been killed, and so were strict vegetarians. Preliminary surveys of the general diet included surprise visits to schools, when all children aged 8-10 were asked what they had eaten during the previous twenty-four hours. Over 90% of the labouring-class Buddhist children had eaten fish. There are some strict vegetarians or lactovegetarians in India or Ceylon, but the great majority are priests or members of the upper classes.

Much has been heard of the sacred cow of India and its alleged uselessness. Until the advent of motors the greater part of all transport and ploughing in India was by oxen or buffalo. On the fodder available in most parts of southern India, the cows produced only enough milk to rear their calves. Less is heard of the useless sacred cow in northern India where cattle flourish and milk is drunk. The more taboos and superstitions are studied the less simple they appear; some have underlying material values, if only for the upper and priest classes.

Dr. Williams writes:

"Many of them must rely on their own rural ability and intelligence in using what is readily available, such as soya or groundnut powder, mango-seed flour, and sweet-potato leaves. At present these people lack the knowledge and the confidence which alone will produce results."

I would add that nutritionists also lack the knowledge.

Pulses have never been used as staple articles of diet in the same way as cereals. Analytical tables do not tell us why dried pulses, taken daily in more than small amounts, lead to indigestion and flatulence. At one time pellagra was common among the poor whites in the southern States of America. Because analyses showed groundnuts to be rich in proteins and vitamins which should prevent pellagra, the people were urged to eat them, and their reply, "we ain't no peanut eaters," was recorded as perversity; but it is not recorded whether those who recommended peanuts had tried them for themselves. Soya beans are better, for, although they contain a bitter principle and are indigestible because of a trypsin-inhibiting factor, and flour made from the roasted bean will not keep, many Chinese use excellent preparations daily in the form of "milk" curds, fermented products, or sprouted beans; but none of these is easily prepared.

In Ceylon I studied 20 or more leaves eaten by the villagers; these were consumed in small amounts, at infrequent intervals, and very few were ever found on the tables of the well-to-do. When I tried the various leaves myself, I found all of them unpleasant, except in small amount. The most edible were basil (*Basella rubra*), tampala (*Amaranthus gangeticus*), swamp spinach (*Ipomoea aquatica*), and centella (*Centella asiatica*); but compared with them, cabbage is a luxury.

Foods from plants, especially leaves, are bulky and contain much indigestible matter; the proteins are of low biological value and only a mixture of several can supply all the nutrients. There are no vegetable foodstuffs which contain all or nearly all the needed nutrients in digestible form, as is the case with milk, eggs, and the whole carcass of an animal. Furthermore, vegetable foods contain a great variety of

non-nutrient substances, and some of these, such as glycosides, saponins, and oxalates, may not be entirely harmless when taken over a long period.

On the other hand, there are no nutrients needed by man which cannot be found in vegetable foodstuffs. Realising this, laboratory workers have studied the possibility of preparing from them a powder equal in nutritive value to dried milk. Discussing this matter of substitutes for milk I have pointed out¹ that such a powder must be far cheaper than milk if it is to be widely used for the children of countries where the family income is only a few shillings per head per month. The bulk of the material can be prepared from cereals, pulses, roots, and oil-seeds. Probably it would be necessary to add synthetic vitamins and perhaps one or more amino-acids. Obviously the powder must be prepared in factories, for it is beyond kitchen practice.

In an attempt to interest manufacturers of foods and vitamins, I wrote two papers in trade journals,² visited many firms, and corresponded with a large American firm which is preparing amino-acids—particularly lysine—in bulk. I thought that firms preparing cheap foods for livestock feeding might be interested. But they all shied at the financial implications when I pointed out that the bulk of the powders must be prepared in the countries where they would be used and would have to be cheap enough for the labouring classes and the indigent to buy.

The shortage of food in many parts of the world is likely to increase with population growth. More than 25 million tons of oil-seeds and nuts are used yearly in the world for the extraction of oil. Oil-cakes, which are rich in proteins and vitamins, are used for cattle food or fertiliser. It should not be beyond the ingenuity of chemists to assemble, in a digestible and appetising form, the nutrients from these cheap sources.

LUCIUS NICHOLLS.

HIGH ISOHÆMAGGLUTININ TITRE IN BLOOD-GROUPS A AND B

SIR,—In investigating the selection of possible test-serum donors, Brewer³ and Rainsford and Morgan⁴ estimated the iso-agglutinin titre in blood of groups A and B. Rainsford and Morgan found the frequency of suitable donors in the British population to be about 1:60 in group A and 1:14 in group B. To determine the corresponding frequency in the Swedish population, 1494 group-A sera and 543 group-B sera from the ordinary blood-donors in Stockholm were titrated for the anti-B and anti-A iso-agglutinin titre respectively.

The agglutinin was first tested in a dilution of 1:100; only those sera which agglutinated macroscopically in this dilution were titrated in a serial dilution of 1:1 to 1:256. Serum A was titrated against B and A₁B blood-cells, and serum B against A₁, A₂, and A₂B cells. All titrations and tests were made on tile.

Of 61 A sera which agglutinated B cells in a dilution of 1:100, 39 agglutinated A₁B cells in a dilution of 1:128 in ten minutes. Of these 39 sera, only 15 agglutinated A₁B cells in a dilution of 1:256, which I consider to be the minimum end-titre of an anti-B serum when the loss of activity during storage is taken into account. Only 4 sera showed a stronger agglutination than a + reaction in a dilution of 1:256 and were regarded as good test-serum donors.

Of the 543 B sera, 39 agglutinated A₁ cells in a 1:100 dilution in fifteen minutes. These 39 sera were titrated against A₁, A₂, and A₂B cells; the results are shown in the accompanying table.

The minimum titre for anti-A serum was taken as 1:128 with A₁ cells, 1:64 with A₂ cells, and 1:32 with A₂B cells. It is seen from the table that 18 B sera fulfilled the minimum requirements. If the loss of activity during storage is taken

NUMBER OF B SERA AGGLUTINATING A CELLS IN TEN MINUTES

Dilution	No. of B sera agglutinating		
	A ₁	A ₂	A ₂ B
1:1	39	39	39
1:4	39	39	37
1:8	39	39	34
1:16	39	38	27
1:32	39	38	18
1:64	39	35	13
1:128	37	20	2
1:256	27	6	0

into account, 13 B sera (which agglutinated A₂B cells in a dilution of 1:64) were suitable as anti-A test sera.

An analysis was made of the sex, age, and Rh-group distribution in the high-titre donors. No correlation was found between the sex and the high titre. There was a preponderance of donors between 20 and 30 years of age. A surprisingly high frequency (30%) of Rh-negative blood (cde/cde) was found in the group-B high-titre sera; no such high frequency was noted in the corresponding group-A sera.

The frequency of suitable test-serum donors in the Swedish population (Stockholm) was found to be 1:100 in those with group-A blood and 1:40 in those with group B.

OLOF RAMGREN.

INTRADERMAL ADRENALINE

SIR,—I was glad to notice Dr. Louis Moss's letter in your issue of March 27.

I have been using this new therapy since he described it in a letter to the *British Medical Journal*. My findings corroborate, to a great extent, those of Dr. Moss. I have found that the intradermal injections, with massage of adrenaline cream, give much relief; and allow the patient to use the affected part much more freely.

This seems to me to be a very easy and simple treatment, which can be carried out by the general practitioner in his surgery or the patient's home. Being both cheap and effective, I think it is well worth trying, and it has enabled me to avoid sending some patients to the busy physiotherapy departments.

London, W.C.2.

W. P. JOHNSTON.

BETTER GENERAL PRACTICE

SIR,—May I draw your readers' attention to the comment in the *Observer* of March 28 on Dr. Stephen Taylor's survey, *Good General Practice*, which was discussed in your leader of March 27?

After a short delineation of the main purpose of the survey, the *Observer* says:

"But one point which emerges incidentally from the findings is that some 10 million people living mostly in industrial areas are receiving from their 5,000 doctors a medical service which leaves much to be desired. It would hardly be going too far to say that some of these doctors—perhaps as many as 1,000—are guilty of serious malpractice. They risk the health and lives of their patients by failing to do clinical examinations at the surgery, and rarely on visits. Some do not even possess an examination couch."

It would appear, therefore, that about £10 million are spent each year in providing a "medical service which leaves much to be desired." It is highly probable that most of the 1000 doctors "guilty of serious malpractice" are earning more than many consultants. They are earning three, four, or even five times as much as registrars who, together with housemen, do much of this type of doctor's work for him.

A conservative estimate suggests that £3 million each year is being paid to and accepted by men who are

- Nicholls, L. *Tropical Nutrition and Dietetics*. 3rd ed., London, 1951; p. 231.
- Nicholls, L. *Food Manuf.* 1950, 25, 95; *World Crops*, April, 1950.
- Brewer, H. F. *St Bart's Hosp. Rep.* 1937, 70, 247.
- Rainsford, S. G., Morgan, W. T. J. *Lancet*, 1946, 1, 154.

"risking the health and lives of their patients by failing to do clinical examinations at the surgery, and rarely on visits."

It is common knowledge that registrars are not wanted in general practice in very many areas, and that a higher qualification, particularly the M.R.C.P., is a grave disadvantage. These registrars find their way blocked in the hospital service too, because there is no money for the new posts which are needed in general medicine, general surgery, and midwifery and gynaecology.

Is it surprising that registrars, many of them in their middle and late thirties, married and with children, and with many years of hospital experience behind them, are becoming increasingly bitter?

SENIOR REGISTRAR.

TUBERCULOSIS YARDSTICKS

SIR,—Dr. Tattersall wrote last week a thought-provoking letter on the subject of tuberculosis control.

The reason why the number of cases of tuberculosis on the chest-clinic registers has increased by 20% during the past five years is almost certainly that the number of chest clinics and the facilities they offer have increased.

Dr. Tattersall states quite correctly that tuberculosis will only be controlled by reducing the number of sputum-positive cases—that is, the "known infector pool." He makes the novel suggestion that the certificates of the Ministry of National Insurance should be made available so that the relapse of previously notified cases should be known. I feel that a more sure way would be for the Hospital Laboratory Service to notify automatically the medical officer of health of the results of specimens of sputum containing tubercle bacilli.

I wonder if it would be possible for patients receiving National Assistance who take their own discharge from sanatoria and move to other towns to be followed up through the National Assistance machinery and so avoid being lost sight of, as so often happens.

Whether or not the patient accepts treatment is his concern, but it is very much the concern of others that he should be taught and practises those rules of hygiene that render him a safe member of society.

Bournemouth.

D. J. AP SIMON.

TREATMENT OF VARICOSE ULCERS

SIR,—At risk of seeming captious, I would like to comment on Mr. Maurice Lee's letter of April 3. Many pretty hypotheses have been advanced by surgeons in connection with venous disorders, and it seems to me that a much more critical attitude should be adopted towards some of the too-readily accepted doctrines of the present day.

Referring to the question of arterial spasm in cases of thrombosis, Mr. Lee states that "the equilibrium between inflow and outflow . . . is further affected by the arterial spasm that *always* accompanies a deep thrombosis" (my italics). In my view there is no justification for this statement. On clinical examination one rarely sees evidence of arterial spasm in cases of venous thrombosis, and this clinical observation is supported by plethysmographic studies I made several years ago on patients in the postoperative period. The latter work was not published, but I can assure Mr. Lee that I was not able to demonstrate reduction of arterial flow to the leg in a small number of patients with thrombosis. Had I investigated more patients, I am sure that occasional examples of arterial spasm would have been seen; it is, however, definitely uncommon.

Mr. Lee goes on to advocate the use of vasodilator drugs in the treatment of varicose ulcers, in the belief that they will promote healing. He says that "lumbar sympathectomy will do the same as intra-arterial injec-

tions of tolazoline, and it will be more permanent in its effect." There is, I believe, no authentic evidence that lumbar ganglionectomy is of any real value in the treatment of varicose ulcers, and I would like to ask Mr. Lee whether his contention about the value of tolazoline is not an unjustifiable assumption based on acceptance of an analogous method of treatment.

Mr. Lee is, I think, guilty of a further over-simplification when he says that "pain becomes less as soon as ulceration occurs, probably because there is then an outlet for accumulated metabolites." Can others agree with his initial contention, and what evidence is there that the outlet of metabolites relieves pain?

Finally, Mr. Lee refers to the lack of success of skin-grafting operations, a view with which few would disagree. Nevertheless, he himself was a keen advocate of darning skin-strips through the granulations of varicose ulcers. I wonder what success he has had with this measure and whether he still believes in it.

I must apologise if I seem to cavil, but the treatment of varicose ulcers is a very important matter and I would earnestly plead for a more critical approach to this subject. The surgical literature abounds with enthusiastic articles on dubious methods of treatment for varicose veins, varicose ulcers, and postphlebotic sequelæ. Since the care of so many of these patients is left to relatively junior people, it behoves us to be especially cautious in referring to doubtful aetiological factors and in advocating new methods of treatment.

Radlett, Hertfordshire.

R. S. MURLEY.

FULL-TIME—PART-TIME

SIR,—The curious letter from two junior part-time consultants (March 27) has stirred me from the undesirable lethargy surrounding a full-time consultant. Undoubtedly there is a need for both types of consultant, and abusing one another does not forward the interests of either. It is obvious that the amount of work done is related to the individual and not to the appointment. The part-timer brings in variety and new experience; the whole-timer, by treating his hospital as a second home, gives it a personal care and interest which could not be expected from a part-timer attending one or two sessions.

As maximum part-time consultants your correspondents do nine sessions. They admit to a mileage of twelve thousand, most of which must be at the Board's expense and from which they should get enough to compensate for the two sessions further they might do on full time. The general experience of consultants with such mileage as this is that they make a good profit on their mileage alone.

A car is equally essential to the full-time surgeon or physician on emergency duty, and the chief bone of contention lies in the failure to recognise this and give him the appropriate allowances, preferably in taxation, for this. It is absurd that, when a doctor's hospital, consulting-room, and home are far apart (so raising his mileage allowance), this offsets the number of sessions lost by changing to part-time. The Board appears to be a double loser, both by losing the services of the doctor in his increased travelling-time, and by actually having to pay him for it. I would like to hear George Schwartz's comments on this arrangement in relationship to solvency in the business world.

The rational way to clearing anomalies and abuse of mileage claims is to allow every medical man a basic allowance for a car, if necessary related to his need to use a car professionally, and to add to this a very much smaller mileage allowance.

The comments of your two correspondents show well the misuse of a doctor's time in travel and in multiple

appointments for a small number of sessions at several hospitals. It also appears a little unfair to protest about the lack of private practice accruing to them from work at a hospital for which they are already fully paid. This was once a fair return for unpaid labour, but old ideas die hard.

I hold no financial grievance against my part-time colleagues, as I realise that the essential difference between our outlooks is whether more money and less time or less money and more leisure represents a higher standard of living. I believe that the widespread impression that full-time consultants get allowances for books and journals, for reprints, for the telephone, for conference expenses at home and abroad, and for the upkeep of their premises should be corrected. Broadly speaking they do equivalent amounts of day labour and bring similar abilities to bear on it. The maintenance of their abilities in first-class order demands the same literary, social, and professional expenses, and this should be recognised. What a doctor does with his overtime is not under discussion.

Northwood, Middlesex.

J. G. BONNIN.

SIR,—It is desirable, as Mr. Langston suggests in his letter of March 27, that there should be no antagonism between whole-time and part-time specialists, but this ideal is unlikely to be achieved while the conditions of whole-time service remain depressed. Consequently, it is up to those part-time consultants who occupy the positions of influence to support whole-timers in their fight for justice. As Mr. Langston was instrumental in securing the election of one whole-time regional specialist to the staff side of Whitley B (for which whole-timers are duly grateful), he must be aware that the other whole-time representative on this committee is a professor of pathology, who, in spite of his distinguished academic record, is not qualified to represent the interests of whole-time specialists in their struggle for existence in the provinces. This fact has been made abundantly clear to all concerned by a letter from Mr. Rufus Thomas, president of the Association of Whole-time Specialists.¹ Incidentally, there are 17 members on Whitley B, so my figure of 15 part-timers is correct.

I am afraid that Mr. Langston's account of the staff side's efforts on behalf of whole-timers does not show events in their true perspective. The announcement of the new mileage rates, which meant increased payments to part-timers and reduced ones for whole-timers, was made in the *British Medical Journal* on Aug. 16, 1952. Subsequently these rates were amended in the General Whitley Council² and whole-timers were placed in the same category as "hospital clerks and porters." It was not until May, 1953, that representatives of the Association of Whole-time Specialists met the management side of Whitley B, for the first and only time. Of course, by then, the victorious management side were not going to surrender the position won, and the few verbal bouquets they distributed to their defeated opponents are nothing for Mr. Langston to rhapsodise about. Surely it is obvious that no whole-timer can have any faith in the staff side of Whitley B unless whole-time regional specialists are adequately represented on it? Mr. Langston himself has criticised the composition of this committee because of the predominant representation of Royal Colleges and Scottish Corporations on it.³ It is, of course, for Mr. Langston and his colleagues holding positions of influence to make this effort to secure unity within the profession, or else to leave the terms and conditions of service to be decided in the political arena, where they have now strayed.

A WORD WANTED

SIR,—We have been arguing about a word! Would your readers care to join in?

We are looking for the best antonym to "retrospective." The word we want is intended to emphasise the differences between the two forms of research: the forward-looking planned research, and the backward-looking survey. Some of the suggestions made were: prolective, prolative, prospective, anterospicive.

Bristol Royal Hospital
for Sick Children.

JOHN APLEY.

NURSING BY THE MOTHER

SIR,—What a pleasure it is to read Mr. Michael Oldfield's letter in your issue of March 20 drawing our attention to the dangers confronting infants and children from the structure and organisation of the hospitals in which they are treated.

"In most hospitals in England," writes Mr. Oldfield, "the child is treated like a miniature adult"; and this was aptly illustrated, for example, when the Sick Children's Hospital in Glasgow was, in a minimum of time, converted into a military hospital, by the substitution of beds for children's cots. The dangers to physical survival, cited by Mr. Oldfield, in wards that contain as many as 35 cots, are paralleled by the dangers to the child's mental and emotional health, studied by Dr. Bowlby and his colleagues. The efforts of Sir James Spence, and those who follow his lead, to make provision for mothers to help in the nursing of their infants, only partially alleviates the conditions. The last few decades have brought so much new understanding of the dynamics of illness in children, that our handling of them in hospital is out of step with our knowledge.

The time cannot be far distant when the construction of new hospitals will be a possibility. Could not the National Health Service call together children's physicians and surgeons and child psychiatrists, together with an architect experienced in hospital construction, to plan a hospital which would be directly designed to meet the specific physical, mental, and emotional needs of infants and children?

Fresh and creative thinking is needed upon the whole problem of the treatment of sick children in hospital. In this should be included reconsideration of the training of the nurses who will care for them and study of the ways in which the help of mothers can be enlisted. Provision should also be made for the use of those recuperative forces in human beings which lie behind the value of "play" in children and the success of occupational therapy in hastening the recovery of inpatient adults.

Such a project would take time, for the problems are knotty, but the very difficulty should be a stimulus to its achievement. We must not let the possibility of building find us without a plan, and, if we start now, we should be ready to meet such opportunity with a coördinated scheme, even if it is at first only on an experimental basis.

Institute of Child Psychology,
London, W.11.

MARGARET LOWENFELD.

SIR,—Needless to say, we agree with Mr. Michael Oldfield's views (as far as they go) on mothers nursing their own infants (March 20). But we do not think the mere presence of the mother will attain the desired result of reducing cross-infection. She must be assigned definite duties and responsibilities of individual nursing, with which neither nurses nor sisters must interfere. There must be the closest coöperation between mother and doctor, with no intermediary. Nurses must of course be responsible for hypodermic injections and the taking of temperatures, but these need not be contaminating. Mothers who have been trained nurses, we occasionally found, did not make good "mother-nurses." We could

not understand this until we discovered that sometimes they smuggled in thermometers and were frightening themselves if the temperature rose a little; and a frightened (or cross) mother makes an ill baby, so close is the bond. Now thermometers are banned. Thus, the psychological effect of the mother's presence may be either very good or very bad. It is the doctor's and sister's business to see that the psychology is trained in the beneficial direction, and nipped in the bud if it is not.

We wish to correct a possible misapprehension which may be gained from reading our paper—that by providing the patient with "one nurse only," we meant a trained nurse as well as his mother. It would avoid any misconception if after the words "one nurse only" were added "namely, his mother."

Our principle of *insulation* by guarding the infant at all points from *foreign* bacteria, while leaving him freely in contact with organisms to which he is either congenitally immune or has, by gradual contact in his home, become acclimatized, is much more practicable and logical than trying to surround him in an open ward with an aura of asepsis by the adoption of a technique which is suitable only for the operating-theatre.

Now, as John Bunyan would say: "Concerning the conquest of cross-infection, there be three great lions, old and very fierce in the path, and their names be Apathy, Fatalism, and Ignorance." Apathy on the part of medical staffs; fatalism by trained nurses (because they see that however hard they try it still occurs); and ignorance on the part of the public. If the latter could be abolished, infection would go with it. Why else do maternity wards now hold the proud position of having the lowest percentage of cross-infection when in these wards it used to be so rife? It is primarily, we think, because the public became alarmed and demanded an improvement. There is always a tendency to think: "This is our system (and a beautiful-looking ward). It is sacrosanct. If an infant cannot fit into it—well it's just too bad for the infant." A Procrustean bed!

There is a fourth lion though, but he is a puny fellow; his name is Money-bags. He blows himself up like the frog till he is as large as a cow, but when Ignorance gets to hear of him he can always deflate him with a few vigorous pricks where it hurts most.

But we disagree with Mr. Oldfield that Wellington is in Australia.

Wellington,
New Zealand.

H. P. PICKERILL.

TREATMENT OF MEGALOBlastic ANEMIAS

SIR,—I was much interested in the article by Dr. Foy and Dr. Kondi (Dec. 19), and particularly in their statement that "it is well known that whereas all megaloblastic anæmias respond to folic acid, not all respond to vitamin B₁₂."

Though this is a widely held opinion, it should be remembered that exceptions have been reported, and that such observations are of importance in any explanation of the relation between these two vitamins in hæmopoiesis. There are well-recorded cases in pernicious anæmia,¹⁻³ while Das Gupta et al.⁴ described a case of nutritional megaloblastic anæmia failing to respond to folic acid but subsequently responding to proteolysed liver. Experimentally, Heinle et al.⁵ have shown that

pig anæmia will only respond to folic acid and vitamin B₁₂ when one acts in the presence of the other, although only very small amounts of the other may be required.

I have seen 2 patients with severe megaloblastic anæmia of pregnancy who failed to respond to folic acid. The first had folic acid (20 mg. daily) by mouth for 17 days with no response, but later did well on oral proteolysed liver (15 oz. over 23 days). The other showed no response to folic acid by mouth for 25 days (420 mg.) or to subsequent parenteral folic acid (15 mg. daily) for 7 days; then vitamin B₁₂ intramuscularly (50 µg. daily) for 7 days produced a good response.

This response might be attributed either to a direct response to vitamin B₁₂ or, as with Heinle's pigs, to the fact that the folic acid already present in the patient's tissues could not act until vitamin B₁₂ was present. This response is of further interest in that megaloblastic anæmia of pregnancy is usually said to be refractory to vitamin B₁₂ and fully responsive to folic acid,^{6,7} although Patel and Kocher⁸ record 5 cases which did respond to vitamin B₁₂ without previous folic acid.

Institute for Medical Research,
Kuala Lumpur, Malaya.

P. W. G. TASKER.

MULTIPLE ADENOCARCINOMA OF ILEUM CAUSING INTUSSUSCEPTION

SIR,—Illingworth and Dick⁹ state that "the special importance of simple tumours of the small intestine is that they frequently give rise to intussusception. Indeed, the vast majority of intussusceptions occurring after infancy are due to this cause. Of malignant tumours, an adeno-carcinoma is the most common. It occurs in the ileum more frequently than in the jejunum. . . ."

An Arab boy, aged 8, was admitted to this hospital for observation on Dec. 22, 1953. His parents stated that he had been passing blood from the rectum. They gave a vague history of constipation and attacks of colicky pain. He was a small boy with a distinct pallor. There were no purpuric spots and no mass could be felt in the abdomen. Rectal examination revealed nothing, and there was no blood on the examining finger. An enema produced a good result but no evidence of blood.

Six days after admission he complained of severe colicky pain and vomited several times. A mass was easily palpable in the right iliac fossa, and acute intestinal obstruction due to intussusception was diagnosed. Under general anaesthesia (chloroform followed by "open" ether) a midline incision was made. The mass was found to be an intussuscepted portion of the ileum. The intussusception had been caused by two tumours which were protruding into the lumen of the bowel; it was easily reduced and the condition of the bowel was excellent. The tumour-bearing portion of the ileum was resected and an end-to-end anastomosis performed. No other tumours were discovered.

Glucose-saline solution was given intravenously for forty-eight hours, during which time he received nothing by mouth. He made an uninterrupted recovery and was discharged from hospital on the tenth postoperative day.

12 cm. of ileum was removed; near each resected end was a solid cauliflower-shaped tumour protruding into the lumen of the bowel. The larger tumour measured 4.2 by 5.2 cm., the smaller one was about the size of a strawberry. They were greyish-white, firm, and elastic. Histological examination of the two polyps showed adenocarcinoma infiltrating the coats of the bowel.

I wish to thank Dr. W. D. Bathgate, hospital superintendent, for permission to publish this case, and the pathologist of the Government Hospital, Haifa, for his examination and report.

Edinburgh Medical
Missionary Society Hospital,
Nazareth, Israel.

Medicine and the Law

Obituary

Compensation without Negligence

AN interesting comment was made by Mr. Justice Finmore in a case at Birmingham Assizes¹ after a claim for compensation had been unsuccessfully brought against Birmingham Corporation on behalf of a small girl who had been knocked down and injured by a corporation bus. The judge suggested that children hurt in traffic accidents should be compensated, whether the driver was at fault or not, either by the driver's insurance company or by the State, and he suggested to the defending solicitor that Birmingham Corporation should offer to compensate the girl although she had lost her case.

1. *Manchester Guardian*, April 2, 1954, p. 11.

Parliament

QUESTION TIME

Medically Unfit

Replying to a question, Mr. H. A. Watkinson, parliamentary secretary to the Ministry of Labour, said that of the 303,400 National Service registrants in the 1930 age-class 9500 were estimated to be medically unfit.

Appointment Systems in General Practice

Dr. BARNETT STROSS asked the Minister of Health how many general practitioners saw their patients, using an appointment system; and, in view of the benefit to doctors and patients, whether he would consider circularising all local executive committees, stating the advantages that would follow in time saved and reduction of cross-infection.—Mr. IAIN MACLEOD replied: This information is not available. It is in my view for doctors themselves, in the light of the particular circumstances of their practices, to decide how far they can use a system which seems, when successfully organised, to have many advantages.

Medical Help for African Colonies

Replying to a question, Mr. OLIVER LYTTTELTON, Secretary of State for the Colonies, said that colonial territories received considerable assistance from the Government in the form of technical advice and under the Colonial Development and Welfare Acts. Assistance from international sources was only supplementary to that provided by the United Kingdom. The following medical and public-health assistance was given to African territories through W.H.O.:

Nigeria ..	(i) Malaria control	Malariaologist and entomologist	Supplies and equipment being provided by U.N.I.C.E.F.
	(ii) Leprosy control	Doctors	do.
	(iii) Yaws campaign	1 consultant	do.
East Africa	Establishment of East African Malaria Institute	1 entomologist, 1 chemist, and 2 field assistants	do.
Kenya ..	3 medical training-schools	Equipment and supplies	—
Uganda ..	(i) Venereal disease survey	Mobile investigation team	—
	(ii) Nutrition survey	Team of clinical and dietetic experts	—
Tanganyika	(i) Medical teaching	Equipment	—
	(ii) Health survey and health improvement scheme in Bukia area	Nutritionist and physiologist	—
Nyasaland ..	Medical training	Equipment for training-schools	—
Somaliiland	Tuberculosis sensitivity survey and B.C.G. campaign	T.B. specialist and 2 T.B. nurses	—

JAMES FRANK COLYER

K.B.E., LL.D. Brist., F.R.C.S., F.D.S. R.C.S.

Sir Frank Colyer, who died on March 30 at the age of 87, early won a reputation in his profession which he continued to serve with distinction for some sixty-five years.

As a student at the dental school in Leicester Square his intense activity, his quick absorption of knowledge, his enthusiasm for sports, and his ability to organise the students' societies, impressed his seniors and his contemporaries. He passed the final L.D.S. examination in 1887 before he was 21. He was an ardent follower of the dean of the school, Morton Smale, who believed that a dentist should have a medical qualification, and in 1889 he took the Conjoint qualification from Charing Cross Hospital. It was at this time that he collaborated with Morton Smale in the publication of his first work *Diseases and Injuries of the Teeth*, which afterwards, under his sole authorship became the well-known *Dental Surgery and Pathology*. The later editions he wrote in conjunction with Prof. Evelyn Sprawson.

After holding a house-appointment and a demonstratorship at the London School of Dental Surgery (now the Royal Dental Hospital) he was elected to the honorary staff, and also to the staff of Charing Cross.

In 1900 he was appointed honorary curator of the museum of the Odontological Society, which he had served since 1893, as secretary and editor of their *Transactions*. When the society became a constituent of the Royal Society of Medicine and the museum was lodged in the Royal College of Surgeons, Colyer still remained as curator and reorganised the specimens in their new home. He was president of the odontological section of the R.S.M. in 1919.

The first world war gave fresh outlet for his skill and energy in the treatment of facial and oral injuries at the Croydon War Hospital and Queen's Hospital at Sidcup and his work was recognised by his election as F.R.C.S. in 1916 and his appointment as K.B.E. in 1920.

Colyer's belief in the Hunterian conception of natural history as comprising the whole animate kingdom found expression in his chief work, *John Hunter and Odontology*, and in his series of lectures on Variations and Diseases of the Teeth of Animals which were published in 1936. His last work, which embodied years of thought and study, was *Old Instruments for Extracting Teeth* (1952).

E. S. writes: "J. F., as he was always called, was a dynamic personality, whose energies were at times even disconcerting. He was an indefatigable worker in many branches of dentistry, and in his teaching—and indeed throughout his life—it was the broad principles of dentistry rather than the minutiae which interested him. After he gave up private practice he made his professional home at the museum of the Royal College of Surgeons. Here he held forth to all and sundry on the wonderful collection he there had under his care. As he matured he mellowed, and dental surgeons not only from London and the provinces, but from all over the world, used to visit him in his underground department."

"The career of Sir Frank Colyer," L. L. points out, "refutes the line 'He tires sometimes that spurs too fast betimes,' for from his early youth the vital urge in him spurred him on without rest into extreme old age. Even when his beloved collection was packed away in the war, like the grand spirit he was, he went on cataloguing any new specimens, writing a description of those specimens in the few cases transferred to the general museum so that students could benefit by their study—fighting against physical weakness, his vitality bore him upright to the end."

Sir Frank Colyer married in 1895 Lucy Olivier Simpson. She died in 1950, and they are survived by a son and a daughter.

Notes and News

LAW AND MEDICINE

In a presidential address delivered before the section of pathology of the Manchester Medical Society on Feb. 10, Dr. T. Blench said that the Law seeks for certainty but Medicine deals with clinical probabilities. Lawyers chide doctors for differing and also for not being willing to differ. While doctors can be sued as a result of their calling, actions against counsel are statute-barred. Laws were made by lawyers who appreciated their difficulties more fully than those of other people. It is clear that lawyers love words and documents, for the former are elastic and the latter rarely satisfactory even when made by lawyers. On the other hand, Medicine, in contradistinction to advocacy, does not lend itself to verbal analysis and verbal agility. Verbal dexterity in a doctor cannot alter the course of a patient's ailment, while in a lawyer it may change his client's outlook on life. Lawyers and doctors, nevertheless, both take to heart their clients' interest, and at times may identify themselves with it too completely.

A STUDY IN COURAGE

PSYCHOLOGISTS urge us to look to experience, and particularly to early experience, for the key to human behaviour. But just when the key is in the lock, and the door seems to be opening on mental health for everybody, along comes some significant case to remind us that the material is at least as important as what befalls it.

Douglas Bader, whose life-story (so far) is told well and simply by Paul Brickhill,¹ comes of courageous but highly temperamental stock: no native equilibrium, no inborn placidity, has buffered him against disaster: he has had to rely on other gifts. As for experience, his was by no means a good start in life: on the contrary. He was the second child, and three days after he was born he and his mother both had measles; immediately afterwards his mother had a major operation; so they were separated from the start. Moreover when he was a few months old the rest of the family returned to India, leaving him with relatives in the Isle of Man. He was not taken out to rejoin his own mother until he was nearly two years old. Brickhill does not tell us whether the relations in the Isle of Man had included a successful substitute for her; but he makes it clear that Bader's mother, deprived of his company in those early months, was not subsequently able to feel as warmly towards him as she did to his elder brother. For a few months after the reunion the good-tempered small boy presented the subdued appearance of the child who does not fit in, and suffered quietly the assaults of his better-loved brother. Then he began to fight back; and has fought for every worthy cause he has encountered ever since. According to Brickhill, he is always driven by a need to prove himself in his own eyes; and this perhaps is his legacy from those early insecure years—years which might have made another child anxious, depressed, timid, delinquent, or destructive. They made Bader into an outstanding example of tenacity and courage. Courage which, when (as a young pilot in the Royal Air Force, in 1931) he lost both legs in a crash, obliged him to learn to walk on artificial limbs without the aid of a stick; which made him fight to be retained in the Service as a pilot, though R.A.F. regulations made no provision for pilots with no legs; which carried him through the disappointed years when, no longer in the Service, he worked in an office; which sent him back joyously to the air as soon as war broke out; which made him, at thirty, one of the best fighter leaders and tacticians, as well as one of the best pilots, among the inspired few—mostly in their twenties—who fought and won the Battle of Britain; which ensured that he would prove a troublesome prisoner of the enemy, and finally brought him—after three years, and still plotting escape—to the rockbound impregnable castle of Kolditz, whence he and his fellow intrants were rescued by the Americans.

Bader has been an inspiration to more than his fellow fighting men: his courage has been a pattern for many people crippled in war, and his concern for them has been practical and direct. The book tells of many occasions on which he has gone out of his way to help such disabled people, and to set them thinking constructively. One child for whom he did this had lost both legs after an accident with

burning petrol. "The boy just doesn't realise how serious it is yet," the father said afterwards to Bader. He replied with passion: "That's the one thing he must never realise. You've got to make him feel this is another game he's got to learn, not something that will cripple him. Once you frighten him with it he's beaten."

This splendid virtue of courage does not subsist in isolation: Bader, as Brickhill shows, is a many-sided turbulent person, loyal to friends, stormy, bewildering, and implacable to enemies. To read the book is to be grateful that there are such men alive; and also perhaps that there are not too many of them. A world populated by such dynamic characters would presumably fly apart.

RHEUMATISM AND DISABILITY

THE sixth annual report of the British Rheumatic Association describes the association's efforts to plead the cause of disabled rheumatic persons and speaks with satisfaction of the appointment of the committee which, with Lord Piercy as chairman, is considering the position of house-bound and potentially part-time workers. In his speech at the annual meeting, here reprinted, Sir Walter Monckton, Minister of Labour and National Service, said that 800,000-900,000 disabled people had been on the Ministry's register under the Disabled Persons (Employment) Act, and that the percentage of disabled persons employed in industry was 5 and in Government service 5½. More than 35,000 men and women had completed courses at the Ministry's 14 industrial rehabilitation units, and 80% of them went on to training centres or into jobs.

Membership of the association costs 10s. a year. Its address is 11, Beaumont-street, London, W.1.

THE HEALTH OF INDIA

THE report on the activities of the Indian Union Health Ministry for 1953-54 indicates that the Government are prosecuting vigorously their planned campaigns against certain widespread diseases. In the B.C.G. campaign, launched in 1948, over 25 million persons were tuberculin-tested and 8 million vaccinated up to the end of 1953. A national malaria control scheme calculated to protect a population of close on 125 million living in endemic areas, by the setting up of 125 malaria control units, came into being during the year. A department of maternal and child health has been established at the All-India Institute of Hygiene and Public Health in Calcutta; this is a co-operative effort by the Indian government and UNICEF. Construction work on the All-India Institute of Medical Sciences is to start towards the end of this year. It will comprise a medical college, a dental college, a nursing college, a postgraduate centre, a 650-bed hospital, and rural and urban organisations to provide centres for field work. An All-India Mental Health Institute is to be founded in association with the Bangalore Mental Hospital. Finally, a central food laboratory is to be established in Calcutta to help implement the projected legislation to prevent food adulteration. The government of India contributed Rs. 1,290,000 last year to W.H.O. and propose paying Rs. 1,297,000 this year. They are also making a voluntary contribution of Rs. 1,500,000 to the UNICEF local office in Delhi.

STERILISATION OF POLYTHENE TUBING

In the past six years the plastic material 'Polythene' has played an important part in medicine, especially as pliable tubing for intravenous infusions. Farquhar and Lewis¹ found that this tubing was satisfactorily sterilised by immersion and storage in cetrimide or benzalkonium chloride; but it could be boiled provided that it was shock-cooled. The first of these two methods is generally used. Colker and Norman² now report that polythene tubing which had been kept immersed in a solution containing 1% cetrimide has "often shown growths of Gram negative spore-bearing bacilli of a saprophytic nature." They describe a method of sterilising lengths of tubing by heat in soda-glass tubes containing distilled water. This method, they say, is easily applied.

3-D. IN MEDICAL ILLUSTRATION

THE April number of *Anæsthesia* contains, as illustration to an article on Injury to the Median Nerve by Prof. E. A. Pask and Dr. J. G. Robson, what is believed to be the first anaglyphic stereogram reproduced in a medical journal. A Royce-Vala-Scope is supplied for viewing it so that the reader may obtain the full three-dimensional effect.

1. Farquhar, J. W., Lewis, I. C. *Lancet*, 1948, II, 244.

2. Colker, J., Norman, R. *Pharm. J.* Feb. 27, 1954, p. 165.

1. Reach for the Sky. London: Collins, 1954. Pp. 384. 16s.

University of Cambridge

The honorary degree of doctor of science is to be conferred on Sir Charles Dodds, F.R.S.

On March 20 the following degrees were conferred :

M.Chir.—* J. F. Bolton Carter, * A. G. Dingley, Alfred Standeven.
M.B., B.Chir.—* A. J. Danby.
M.B.—A. D. Thursz.

* By proxy.

National University of Ireland

The honorary degree of LL.D. is to be conferred on Dr. E. P. Carey and Dr. Philip Lynch.

Royal College of Surgeons in Ireland

At recent examinations the following were successful :

F.R.C.S.I.—D. F. Doherty, J. Kyle, J. G. Maher.
D.C.H.—B. P. K. Ryan, J. B. Shea.
D.O.M.S.—R. E. Tingey.
D.P.M.—E. Casement, A. C. Fleming, J. P. F. Fogarty, D. C. Hutchison, K. A. McDaid, P. J. Mehan, R. R. Steinert.

Irish Conjoint Board

On April 2 the following candidates, having passed the final examination of the Irish Conjoint Board, were admitted licentiates in medicine and midwifery :

Una E. Batt, A. I. Booth, S. A. A. Carson, Dinshaw Ratanji Ohnoy, Margaret T. Coyle, Laura Cullen, Veronica O. Egbuna, Bridget Finnegan, Patricia J. Finnegan, P. D. N. MacAllister, Grainne McCarthy, P. J. Ward.

West Midlands Physicians Association

A meeting of this association will be held at The Royal Salop Infirmary, Shrewsbury, on Saturday, May 8, at 11 A.M.

Diabetic Association

Dr. K. Hallas-Møller (Denmark) will deliver the Banting lecture at University College Hospital School, London, W.C.1, on Friday, July 16, at 2.30 P.M. He will speak on the New Insulins.

International Congress on Thrombosis and Embolism

This congress is to be held from July 20 to 24, at Basle. Those who wish to read papers should write to the general secretary of the congress, Gynaecological Clinic, Basle University, Basle, Switzerland, before May 31.

British Association of Physical Medicine

The annual meeting of this association is to be held at King's College Hospital, London, S.E.5, on April 30 and May 1. The programme includes a discussion on the Scientific Approach to be opened by Dr. A. C. Boyle, Dr. A. T. Richardson, and Dr. Richard Doll.

Grove Hospital, Tooting

This hospital, which was formerly in the South West Metropolitan region, has now been included in the group which forms the teaching hospital of St. George's.

International Festival of Medical Scientific Films

Minerva Medica has organised this festival, which will be held in Turin from May 29 to June 6. Further particulars may be had from the secretariat of *Minerva Medica*, Corso Bramante, 83, Turin, Italy.

Mental After Care Association

The annual general meeting of this association will be held on Thursday, April 8, at Burlington House, Piccadilly, London, W.1, at 3.45 P.M., when the Very Rev. A. C. Don, D.D., and Dr. Henry Yellowlees, will speak.

General Register Office

Mr. Bernard Benjamin, F.I.A., has been appointed chief statistician (civil) in the General Register Office, in succession to Mr. V. P. A. Derrick, who has retired after 34 years in the department.

Congress of World Federation of Occupational Therapists

This congress is to be held in Edinburgh, from Aug. 16 to 21, under the chairmanship of Prof. Norman Dott. The speakers will include: Dr. Henry H. Kessler (New Jersey), Dr. H. Hoyle Campbell (Toronto), Dr. M. A. Perlstein (Chicago), Sir David Henderson, Prof. Walter Mercer, Dr. W. A. Murray, Mr. Robert Stirling, and Mr. G. A. Pollock. Further particulars may be had from the secretary of the congress (Miss Waterston), Astley-Ainslie Hospital, Edinburgh.

International Conference of Geographical Pathology

The International Society of Geographical Pathology is to hold its 5th conference from Sept. 6 to 10 in Washington, D.C. The general subject chosen for discussion is the Geographical Pathology of Cancer. Further information may be had from Prof. Robert A. Moore, M.D., Washington University School of Medicine, 660, S. Kingshighway, St. Louis, 10, Missouri, U.S.A.

Sir Lionel Whitby, Prof. John McMichael, and Dr. P. M. F. Bishop are visiting the Near East under the auspices of the British Council to attend the fourth Middle East Medical Assembly at Beirut from April 9 to 11.

The Proceedings of the conference held last year in Glasgow by the National Smoke Abatement Society are now obtainable (price 7s. 6d.) from the society, 30, Grosvenor Place, London, S.W.1.

CORRIGENDUM—The article on the Mental Health Research fund (see *Lancet*, March 13, 1954, p. 559) appears on p. 10 of the supplement to the January issue of the *Journal of Mental Science*.

Diary of the Week

APRIL 11 TO 17

Monday, 12th

ROYAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Air Commodore T. C. MacDonald, Dr. I. J. Corbett :
Medical Aspects of Air and Sea Travel.

Tuesday, 13th

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Section of Psychiatry*. Dr. D. A. Pond : New Physiological Data Bearing on Problems of Consciousness. Dr. Denis Williams : Affective Disorders and the E.E.G.

Wednesday, 14th

ROYAL SOCIETY OF MEDICINE
4.30 P.M. *Section of Physical Medicine*. Dr. Doris Baker : Changes in Skin Collagens—A Source of Rheumatic Pains. (Presidential address.)
HARVEIAN SOCIETY OF LONDON, 11, Chandos Street, W.1
8.15 P.M. Dr. George Warren, Dr. Michael Ward : Health at High Altitudes.
NORTH-WESTERN TUBERCULOSIS SOCIETY
5.30 P.M. (Aintree Hospital, Liverpool, 9.) Mr. Dillwyn Thomas : Tuberculous Mediastinal Lymph-glands.

Appointments

BURNS, J. P. J., M.C., M.B. Belf., D.P.H. : senior asst. M.O., Wembley and Willesden.
GOLEN, Z., M.B. Polish School of Medicine, Edin. : asst. psychiatrist, Whittingham Hospital, Preston.
LOFTUS, ANTHONY, L.R.C.P.I., D.P.H. : asst. M.O.H. and asst. school M.O., Oldham.
MACLEOD, WILLIAM, M.B. Edin., M.R.C.P.E., D.M.R.-D. : consultant radiologist, Royal Hospital for Sick Children and Deaconess Hospital, Edinburgh.
NABARRO, J. D. N., M.D. Lond., M.R.C.P. : asst. general physician, Middlesex Hospital, London.
ROUSSAK, N. J., M.B. Manc., M.R.C.P. : consultant physician, Withington and Wythenshawe hospitals, Manchester.
North East Metropolitan Regional Hospital Board :
CROCKET, R. W., M.B. Glasg., F.R.F.P.S., M.R.C.P., D.P.M. : part-time consultant psychiatrist, Oldchurch and St. George's hospitals, Hornchurch.
GRUNBERGER, GEORGE, M.D. Basle, D.L.O. : part-time consultant E.N.T. surgeon, St. Margaret's Hospital, Epping, and Honey Lane Hospital, Waltham Abbey.
MARTIN, D. V., M.R.C.S., D.P.M. : full-time consultant psychiatrist and deputy physician superintendent, Claybury.
MASON, MARGARET M., M.B. Camb., F.R.C.S. : part-time consultant E.N.T. surgeon, Ilford and Barking group of hospitals and clinics.
O'SULLIVAN, J. J., M.B., M.R.C.O.G. : part-time consultant gynaecologist, Whipps Cross Hospital.
PRITCHARD, G. C., M.B. Camb., F.R.C.S., D.O.M.S. : part-time consultant ophthalmic surgeon, East Ham Memorial Hospital.
THORNE, N. A., M.D. Lond., M.R.C.P. : part-time consultant dermatologist, Mile End Hospital, St. George-in-the-East Hospital, and St. Andrew's Hospital, Bow.

Births, Marriages, and Deaths**BIRTHS**

BIHARI.—On March 27, at University College Hospital, to Mae (née McMullan), wife of Julian Bihari, F.R.C.S.—a son (David Julian).
JENNETT.—On March 25, at Liverpool Maternity Hospital, to Dr. Sheila Pope, wife of Mr. Bryan Jennett, F.R.C.S.—a son.

THE SECRETIONS OF THE BRAIN*

RELATION OF HYPOTHALAMUS TO PITUITARY GLAND

S. ZUCKERMAN

C.B., M.A. Oxfd, M.D. Birtn., D.Sc. Lond., F.R.S.

PROFESSOR OF ANATOMY, UNIVERSITY OF BIRMINGHAM

(Concluded from p. 743)

The New Secretions of the Brain

THE PITUITARY HORMONES

The story re-opens in 1895 with the demonstration by Oliver and Schafer that the blood-pressure of an animal rises after the injection of a "concoction" of the pituitary. Howell (1898) soon showed that the effect was due to the posterior as opposed to the anterior lobe of the gland. A few years later Magnus and Schafer (1901) found that the posterior-lobe hormone also has a diuretic/antidiuretic action. And soon afterwards, Dale (1906, 1909) demonstrated that posterior-lobe extracts had an oxytocic action. Concurrently, numerous clinical observations indicated very clearly that the anterior part of the pituitary also had important hormonal functions (see Teel and Cushing 1930). The proof of this was provided in the '20s by the brilliant experimental studies of Herbert M. Evans, Zondek, Aschheim, and others too numerous to mention, which showed quite clearly that the anterior lobe of the pituitary plays a vital part in the control of growth, in the regulation of reproductive processes, and in the maintenance of certain other endocrine organs such as the adrenal cortex.

The histological structure of the posterior lobe did not encourage any of the earlier workers to believe that the active principle which could be extracted from it was elaborated within it. Herring (1908, 1914), whose name is now applied to the hyaline bodies often seen in the pituitary stalk, held that the posterior-lobe hormone was, in fact, produced by the cells of the pars intermedia, and that it passed back into the pars nervosa and up the pituitary stalk. His interpretation was seized upon by many other workers, and particularly by Harvey Cushing (e.g., Cushing and Goetsch 1910, Cushing 1933). Cushing's belief was that the posterior-lobe hormone not only entered the blood-stream, but that after making its way up the pituitary stalk it passed through the ependymal lining of the third ventricle and so entered the cerebrospinal fluid. Gradually, however, opinion changed. The conventional view today is that there are specific parenchymatous secretory cells in the neurohypophysis, and that these cells are responsible for the secretion of the posterior-lobe hormones (see Gersh 1939).

About the secretory powers of the anterior lobe there never was any doubt. Its structure was clearly glandular, and the only difficulty was to reconcile its apparent cytological simplicity with the complexity of its hormonal functions.

By the time we were fairly clear about the distinction between posterior and anterior lobe function, the infundibular region of the brain again entered the

picture. It did so first as a result of a series of studies started by Karplus and Kreidl in 1909, which showed that stimulation of the hypothalamus led to a number of autonomic effects (e.g., changes in heart-rate, and salivation). These observations were followed in 1913 by Camus and Roussy's demonstration that an adiposogenital syndrome could develop as a result of experimental hypothalamic lesions. As our knowledge continued to grow, it became abundantly clear that in some mysterious way the hypothalamus—the infundibular region of the Ancients—controlled or modulated the endocrine activity of both the anterior and posterior lobes of the pituitary. Once again the question was, How?

This time, however, the problem was both more specific and more complicated. First, it was quite clear that the pituitary consisted mainly of two quite separate endocrine structures—an anterior lobe,¹³ and a posterior lobe.¹⁴ Secondly, by now there was precise knowledge of the nature of nervous action; if the pituitary stalk was not hollow, at any rate it consisted largely of the axons of hypothalamic nerve-cells, which provided an anatomical basis for whatever cerebral control there was of pituitary function (see fig. 3). And thirdly—and most important—answers could no longer depend on speculation based on dogma, however hallowed; the hard facts of observation and experiment were needed.

HYPOTHALAMIC CONTROL OF THE POSTERIOR PITUITARY

The first problem for which a solution seemed to have been found was the control exercised by the hypothalamus over the secretion of antidiuretic hormone. The

13. More correctly designated the pars distalis of the adenohypophysis, of which the other two parts are the pars intermedia and pars tuberalis.
14. Now defined as the processus infundibularis of the neurohypophysis, whose two other parts are the infundibular stem or stalk, and the median eminence of the tuber cinereum—which includes the infundibular bulb or infundibulum.

Fig. 3—Diagram to indicate the relations of the pituitary gland to the hypothalamus. The three hypothalamic nuclei mentioned are shown schematically.

*The seventh Addison Memorial Lecture, delivered at Guy's Hospital, London, on Dec. 16, 1953.

explanation seemed simple enough (Fisher et al. 1938). All levels of the neurohypophysis are connected with the terminations of the axons of cells in the nuclei supraopticus and paraventricularis of the hypothalamus (particularly the former). Presumed secretory cells ("parenchymatous glandular cells") are present in the median eminence and infundibular stem, as well as the infundibular process (Gersh 1939). The whole neurohypophysis, including, as it does, part of the floor of the third ventricle, is thus concerned in the secretion of hormone, and all of it is under the control of the hypothalamus. Sever the pituitary stalk, and the part of the neurohypophysis distal to the section atrophies completely—owing to the interruption of the trophic influence of the hypothalamus—and no longer can any hormone, antidiuretic, pressor, or oxytocic, be extracted from it. Destroy the nuclei supraopticus and paraventricularis and remove that control completely, and the whole neurohypophysis involutes; and diabetes insipidus supervenes, owing to the cessation of secretion of antidiuretic hormone. Or completely divide the supraoptico-hypophysial tract, and the cells of the nucleus supraopticus degenerate. The reason why hypophysectomy itself is only occasionally followed by diabetes insipidus is also straightforward; the operation very rarely removes all of the neurohypophysis, and the cells of the part which remains hypertrophy to compensate for the loss of the rest.

These observations and interpretations seemingly provided all that could be asked for in trying to understand the control exercised by the hypothalamus on the diuretic/antidiuretic balance. And since the hypothalamus is a major autonomic motor centre which is linked, as far as one knows, with all the afferent zones of the brain, they also made it possible to understand how various forms of afferent stimulation are tied up with processes in which posterior-lobe hormones are involved. Thus they help to provide an explanation for the effects of emotion on water diuresis (e.g., Verney 1947, Noble et al. 1950, Taylor and Noble 1950), and also to understand the nature of the nervous pathways concerned in the reflex stimulation of milk discharge (Harris 1951). In short, while one might not know exactly how it all worked, there could be no doubt about the general nature of the link between the brain and the posterior pituitary.

HYPOTHALAMUS AND ANTERIOR PITUITARY

If the connection with the posterior lobe of the pituitary seemed, on the face of it, clear enough, that with the anterior was anything but obvious. Here one goes on being confronted by a most bewildering puzzle. First, there is no doubt that the anterior lobe of the pituitary regulates several bodily processes, and that the timing and intensity of its different physiological activities accord with the steps of those processes; or, to put it in the teleological terms used by Bayliss and Starling (1904), that the secretions of the anterior lobe are regulated by the needs of the body. We know that some of this regulation is effected by hormonal or metabolic interaction. For example, when, under the stimulus of the gonadotrophic hormone of the anterior pituitary, an excess of oestrogen is secreted by the ovaries, the pituitary becomes inhibited, and the gonadotrophic stimulus weakens. Or if we follow Wilhelmi (1948), when the peripheral carbohydrate level falls, adrenocorticotrophic hormone (A.C.T.H.) is released from the pituitary, as part of the mechanism concerned in stabilising peripheral carbohydrate levels; then, as an effect secondary to the subsequent secretion of hormone by the adrenal cortex, gluconeogenesis occurs and the level of blood-sugar rises. But some regulation is undoubtedly of a more direct nervous kind, and is presumably mediated by the hypothalamus. For example, it has been shown (Harris 1948a) that in an animal such as a rabbit, which normally

ovulates after the stimulus of mating, direct unipolar or bipolar stimulation of the hypothalamus can result in rupture of the ovarian follicles, provided the experiment is done during the oestrous phase of the cycle. Presumably normal mating also starts a train of nervous stimulation which culminates in the firing of the relevant hypothalamic neurons. Another example is the anoestrous ferret, which becomes oestrous in the winter months if it is exposed to additional light. While the main visual centres of the brain are apparently not involved (Le Gros Clark et al. 1939), the primary receptor for the response is the retina (Thomson 1951, 1954), and the stimulus is presumably also relayed to the hypothalamus before it activates the pituitary. And to take a last but perhaps now more familiar, even if more debatable, example, a painful stimulus leads to a reflex release of A.C.T.H. from the anterior pituitary; certain workers (e.g., de Groot and Harris 1950, Fortier 1952) believe that the hypothalamus is once again an intermediate station for the response.

But—and here is the essential difficulty—few workers believe that the glandular cells of the anterior lobe obtain their secreto-motor innervation from the hypothalamus (see Harris 1948b),¹⁵ or that there is any other kind of secreto-motor innervation (e.g., via nerve-fibres along the pituitary blood-vessels).

How, then, are the "reflex" responses of the anterior pituitary controlled?

THE PITUITARY-PORTAL VEINS

The possibility which is now attracting the greatest attention is that the critical anatomical link between the hypothalamus and anterior pituitary is provided by the very axial-stalk vessels which Lieutaud described nearly two hundred years ago. The part they played then was as a channel for the pituitary; they derive their present importance from the possibility that they convey a so-called "chemotransmitter" from the hypothalamus to the pituitary.

We owe their rediscovery, and their first fairly complete description, to Popa and Fielding (1930a and b, 1933), who gave an account of what they were the first to call the hypophysio-portal system of veins. According to these workers, the axial-stalk veins collect blood inferiorly from the pars distalis (anterior lobe) and pars intermedia, as well as from the pars tuberalis and pars posterior, and then ascend the stalk as parallel veins "which after a short course, acquire thick neuroglia sheaths." Popa and Fielding believed that superiorly, beneath the infundibular recess of the third ventricle, the vessels lost their neuroglia wrapping, and formed a network of very fine channels which they describe as a secondary distributing net. Popa and Fielding were persuaded of the correctness of Cushing's opinion about the direction of flow of the posterior-lobe hormone, and it was their view that the current in the portal vessels was from below upwards, and that colloid material was transported from the pituitary to the hypothalamus, where in fact they demonstrated it histologically, as had Collin (1928) before them. Since then the contrary view has gained ground, particularly as a result of the researches of Wislocki and King (1936), Green and Harris (1949), and Barnett and Greep (1951a); and most—but not all—observers now believe that the direction of the blood is from above downwards. The secondary distributing net of Popa and Fielding has thus become the primary net, comprising a dense mesh of capillary loops in the pars tuberalis, while the true secondary net is represented by the connection

15. The early death in 1952 of Vazquez-Lopez, the most recent protagonist of the opposite view, has unfortunately removed from the scene one who might have helped solve the problem, which has clearly to be settled before we are going to reach anything like a final answer to the question of the control of anterior pituitary function.

of the main portal vessels with the sinusoids of the pars distalis (see fig. 3).¹⁶

As already indicated, it was the disbelief in the existence of any nervous connection that made it necessary to consider the possibility that the pituitary-portal veins are in some way involved in the presumed control which the hypothalamus exercises over the anterior lobe of the pituitary. The hypothesis that has been advanced (Harris 1948b) is that some unknown "chemotransmitter" is liberated, as a result of nervous stimulation, in the vicinity of the portal vessels, into whose primary capillary loops it passes. The "hormone" then passes down the longitudinal channels on the stalk into the sinusoids of the anterior lobe, and is so able to influence the secretory cells of the pars distalis.

In the light of Harris and Jacobsohn's (1952) experiments on pituitary transplantation, few could doubt that the portal vessels play some special part in the economy of the anterior lobe; for these two workers found that pituitary tissue is more likely to "take" successfully if it is transplanted under the median eminence of the brain, where the grafted tissue can come into relation with the proximal stumps of the portal vessels, than anywhere else. On the other hand, the attractive theory of which the portal vessels constitute the central feature is essentially based on what may be called purely negative considerations. Indeed, the chemotransmitter or chemotransmitters had to be conjured into existence only because without them we could seemingly explain nothing about the mechanisms involved. Moreover, the theory is hardly as precise as the facts which it has to explain. The anterior lobe of the pituitary controls many functions; and we have either to suppose that the gland is differentially activated by different kinds of chemotransmitter, or that, once activated by a single stimulus, the gland of itself adjusts its secretions according to the needs of the body. If it is the former which is implied, we are well beyond the area of fact. If it is the latter, the hypothesis merely transfers the critical problem we are trying to understand—how the reflex functions of the pituitary are controlled—from the hypothalamus to the pituitary itself.

THE PITUITARY-PORTAL HYPOTHESIS

The specific evidence which it has been suggested (Wingstrand 1951a,¹⁷ Harris 1952, Mazzi 1952) supports the idea that the pituitary-portal vessels are the controlling link between these two structures, derives partly from observations on the effects of direct stimulation of the hypothalamus, partly from studies of the behaviour of pituitary grafts, and partly from studies of the effects of section of the pituitary stalk.

The first line of evidence, however, merely indicates that experimental stimulation of the hypothalamus can lead to responses such as ovulation—without in any way showing what the link is between the hypothalamus and the anterior pituitary. Correspondingly little can be drawn from such evidence as is available about the behaviour of pituitary grafts. The genetic relationship of host to donor has not always been as close as is desirable in experiments of this kind, and the results in some cases reflect the fact that very little pituitary tissue has survived. All but a few reports also imply that the

grafts do not maintain full reproductive function. On the other hand, it seems to be agreed that a transplant of anterior pituitary tissue in the anterior chamber of the eye will release A.C.T.H in response to a suitable stimulus—in spite of the fact that it is completely separated anatomically from the hypothalamus.

The information that is available from experiments in which the pituitary stalk has been sectioned is also equivocal, some observers reporting very little, if indeed any, and others considerable, derangement in processes which are under the control of the anterior pituitary (e.g., reproduction). Harris (1952) has suggested that in those instances in which the operation has not interfered with reproductive function, the pituitary-portal vessels have regenerated; and on the basis of work carried out in collaboration with Jacobsohn (1952) he has concluded that the anterior pituitary does not function properly except when the pituitary-portal system is intact. An alternative explanation of the conflicting results of stalk section reported by different investigators is that the operation almost inevitably divides one or more small vessels supplying the gland, with variable amounts of resulting and lasting damage due to infarction (Greep and Barnett 1951).

Studies in my own laboratory (Thomson and Zuckerman 1953) suggest that complete division of the pituitary stalk in the female ferret does not necessarily interfere with the presumed relay of impulses to the pituitary from the hypothalamus—even when no vascular connection of any kind has re-formed between the gland and the infundibular region. The particular response studied was the reaction of the anaestrous animal to additional light in the winter months. The operations were carried out in the summer months, and a piece of waxed paper inserted between the proximal and distal parts of the stalk. Most preparations were defective for one or other of several technical reasons—usually movement of the paper between the time of the operation and the subsequent autopsy. In two, however, there was no question but that the animals reacted to light despite either destruction of the median eminence and disappearance of the primary capillary net, or complete separation of the pituitary from the hypothalamus, determined from serial sections of a block consisting of the sella turcica, the pituitary, and the overlying part of the brain. In one animal a three-dimensional reconstruction showed that the paper was still in position, that the processus infundibuli had atrophied completely and that the proximal stump of the stalk was attached to the scar tissue surrounding the plate of paper. The pars distalis, which the paper completely separated from the base of the brain, showed no histological abnormalities, and was normal in size. There was no vascular connection of any kind between it and the region of the median eminence.

This observation disposes both of the view that the integrity of the pituitary-portal veins is essential for the "reflex" activation of the anterior pituitary in responses of the kind that we are considering, and of the generalisation that the anterior lobe of the pituitary will not function properly unless the vessels are intact. It is also incompatible with the idea that the signal which triggers the pituitary of the anaestrous ferret to produce gonadotrophin is some chemotransmitter that is elaborated in the hypothalamus, and which passes down the pituitary-portal veins. On the other hand, it does not exclude the possibility that there is a chemotransmitter(s), or, given that one exists, that this is conveyed to the pars distalis via the systemic blood-stream. Nor, needless to say, do our observations mean that what applies to the ferret necessarily represents general vertebrate physiology. In many birds, for example, all or most of the arterial blood which passes to the pars distalis traverses the capillary loops of the primary capillary net of the portal system, and in the species concerned these vessels are presumably

16. Popa and Fielding (1933) knew that other observers before them had seen the hypophysio-portal vessels. They do not, however, appear to have known about de Bordeu's controversy with Lieutaud, since the earliest of their references is to Lothringer (1886), who described an intermingling of epithelial cells with large vessels at the point where the pars distalis and pituitary stalk come together.

17. Wingstrand, while adhering to the pituitary-portal hypothesis, recognises that "the decisive proof of the route of the impulses from the hypothalamus to the pituitary is lacking."

essential to normal pituitary function (Wingstrand 1951a and b, Benoit 1951).

Our observations do, however, underline the critical consideration that what matters in experiments in which the stalk is divided may well be the extent to which the anterior pituitary suffers as a result of infarction, following on the interruption of its ordinary blood-supply, or from some other cause. In the rat Greep and Barnett (1951) and Barnett and Greep (1951b) found that immediately after the operation the reproductive system becomes hypoactive to an extent which varies with the amount of damage suffered by the anterior pituitary, but that it may then recover slowly, although rarely completely. Recovery is, however, independent of restoration of the pituitary-portal vessels. Tang and Patton (1951), on the basis of experiments on male guineapigs, go a step further and state that there is practically no evidence of impairment of anterior pituitary function after stalk section, and that this is so despite no regeneration of the stalk vessels. In ferrets whose pituitary stalks are divided, the anterior lobe is occasionally normal in size, and at other times smaller and changed in microscopic appearance. In the former, but not the latter, instance the operation has presumably damaged some small vessels supplying the gland.

The fact is that no two operations on the pituitary stalk of an animal are likely to produce precisely the same type of lesion—regardless of the intention of the investigator. Circumstances make it difficult to standardise the operation, and variation in minute anatomical disposition between animals cannot be counterbalanced by visual control. Moreover, unfavourable though the position is with mammalian species used in experiments on the stalk, it appears to be worse with birds, where the main afferent blood-supply to the pars distalis is, apparently, via the portal vessels. Experiments may show that anterior-lobe function is not the same after division of the portal vessels, and one may consequently draw the conclusion that some local chemotransmitter is involved (Benoit 1951). A more obvious interpretation would, however, be that an ischaemic anterior lobe cannot function properly.

In evaluating experiments of the kind we are discussing, it is clearly not enough, therefore, to be told that the stalk was completely divided. Where pituitary hypo-function supervenes, we also need to decide whether the effects observed were not due to unintentional damage to the pars distalis, or even to damage to adjacent parts of the hypothalamus.

While our observations on the ferret conflict with the pituitary-portal hypothesis, they fail to take us a single step closer to an understanding of the precise way the response to light in this animal is, in fact, mediated. And unless we are prepared to overlook the critical lack of those facts which should be there if we are to understand the physiological mechanism involved, the same unfortunate conclusion applies, in my judgment, to all experiments which seem to show how the hypothalamus is linked to, and is involved in, the "reflex" activation of the anterior lobe.

SECRETIONS OF THE HYPOTHALAMUS

It is paradoxical that while the "chemotransmitters" which activate the anterior lobe seem so illusory, an increasing number of researches in recent years are nevertheless leading to the view that hypothalamic neurons do, in fact, secrete hormones. These, however, are concerned with the neurohypophysis—not the adenohypophysis. I have already referred to the fact that Collin, as well as Popa and Fielding, had noted that so-called colloid inclusions could be found in the hypothalamus. E. Scharrer independently made the same observation, and in 1928 published the first of a series of papers concerned with the peculiar secretory appearance

of cells in the nuclei supraopticus and paraventricularis of the vertebrate hypothalamus, and with their close relationship to capillaries. He argued convincingly that the histological appearance of neurosecretion had a functional significance, and represented neither post-mortem changes, nor degeneration phenomena, nor fixation artefacts; and also that the colloid in the hypothalamic nuclei had not migrated into the brain from the pituitary, as had been suggested by Collin. Few, however, seem to have been convinced, and Scharrer, as he himself states (Scharrer and Scharrer 1940) failed to throw further light on the problem by experimental methods. It was, as he points out, difficult to know what pharmacological tests to apply to extracts of the two hypothalamic nuclei. At the same time the contention of Ranson and his colleagues that the hypothalamus could not take over the function of the neurohypophysis, when the latter was ablated, obviously affected views on the possible significance of the hypothalamic secretion.

The position was transformed overnight in 1949, when Bargmann discovered that Gomori's chrome alum-haematoxylin-phloxine stain could be very effectively used to demonstrate cytoplasmic inclusions not only in the neurons of the nuclei supraopticus and paraventricularis, but also throughout the length of their axons. His observations have now been confirmed by many workers, including Scharrer and his colleagues. No neurons other than those of these two nuclei and of the mammillo-infundibular nucleus are chrome-haematoxyphil¹⁸ (Smith 1951). At the same time, experiment has suggested very strongly that the neurohypophysis itself is not a primary secreting organ, but that the posterior lobe hormones (the pressor, antidiuretic, and oxytocic principles) are elaborated by the neurons in the nuclei supraopticus and paraventricularis, and also possibly by their axon terminals in the neurohypophysis (e.g., Bargmann and Scharrer 1951, Hanström 1952a and b). For example, it has been shown (Hild 1951, Stutinsky 1951a) that when the pituitary stalk is tied or cut, the part of the neurohypophysis distal to the ligature rapidly becomes depleted of material which stains with Gomori's alum-haematoxylin, whereas so-called Gomori-positive material accumulates within the axons immediately proximal to the ligature. Corresponding observations, which seem to indicate that there is a flow of some substance from the cell body down the axon, have been made in invertebrates in which "neurosecretion" has for long been accepted as a normal phenomenon. For example, Ellen Thomsen (1954) has used a single strand of silk from the silkworm to ligature the axons coming from a few secretory neurons in the brain of the fly, and has demonstrated the damming-back of some substance immediately proximal to the knot. Yet another demonstration of this "flow" has been provided by Drager (1950), who removed the pituitary from a certain species of snake and filled the empty sella turcica with fibrin-foam. Two to four weeks later, when the animals were killed, spherical droplets with staining properties identical with those of the granules in the hypothalamic nuclei, were found in the fibrin-foam.

Transplantation experiments also suggest that the process infundibuli does not secrete the hormone it contains. Thus, Stutinsky (1950, 1951b) transplanted the "gland" to the capsule of the kidney, and found that in its new position it rapidly becomes depleted of Gomori-positive material which, on the other hand, piled up in the proximal part of the neurohypophysis which was not removed. A corresponding observation is based on the

18. The following terms have been used to describe cells which stain electively with chrome alum-haematoxylin: Gomori-positive; C.H.P. positive; chrome-haematoxyphil. Smith states that the axons of the mammillo-infundibular nucleus mingle with those of the two other nuclei which react to the stain.

fact that neurosecretory granules disappear from the hypothalamus and neurohypophysis when animals are kept thirsty. If the pituitary stalk is cut in such animals, which are then allowed to drink ad lib, granules soon reappear proximal to the cut, but not in the part below (Hild 1953). Moreover, the granules first reappear in the cell bodies themselves, as opposed to the axons (Ortmann 1951).

Valuable evidence has also been obtained in a series of experiments carried out on large groups of Alsatian dogs by Zetler (1953) and Hild and Zetler (1953). These workers have found that the concentration of posterior lobe hormone in the anterior hypothalamus¹⁹ varies, in parallel with that in the processus infundibuli, according to the state of hydration and dehydration of the body. They have also shown that, whereas the concentration of posterior lobe hormone is much higher in the normal processus infundibuli than it is in the hypothalamus, the reverse is true after the pituitary stalk is tied. The concentration of hormone distal to the ligature rapidly falls, while that in the hypothalamus increases. Zetler and Hild have also provided evidence that the substance which has an affinity for Gomori's chrome alum-haematoxylin is almost certainly not the active hormone, but some carrier material. This observation is interesting in view of the recent synthesis by du Vigneaud (1953) of polypeptides with the properties of posterior lobe hormones.

The general conclusion to which all these newer studies are pointing is that the posterior lobe itself is little more than a storage organ for hormones produced in hypothalamic nuclei. On the other hand, Bodian (1951), in a very careful reassessment of the histological structure of the neurohypophysis of the opossum, holds that, while this conclusion is in general true, the terminals of the axons in the tractus hypophysius may also be involved in the process of secretion. Bodian believes that "the morphological complexity of the nerve terminals becomes more readily rationalised as a mechanism for serving to increase the ratio of cell surface to cell volume, and perhaps thus favoring an enhancement of the secretory process in the pars nervosa, as compared with the hypothalamic nuclei." He also believes that the pituicytes (Gersh's parenchymatous secretory cells) are adapted so as to bring the nerve-fibre terminals into closer relationship with the blood-vessels which intervene between the lobules of the processus infundibuli.

The idea that the axon terminals may play a part in the secretory process can be related to some recent observations of Vogt (1953). This worker has found that extracts of the anterior hypothalamus have the same ratio of pressor to antidiuretic activity as characterises true posterior-lobe extracts, but that oxytocic activity is relatively very low. She has, therefore, suggested that the "molecule" of posterior-lobe hormone secreted by the anterior hypothalamus is either modified as it travels down into the processus infundibuli, or that the latter actually elaborates oxytocin. Either way, this experimental observation could be taken as according with Bodian's anatomical view that the nerve terminals play some active part in the production of the posterior-lobe hormone.

EVIDENCE FOR POSTERIOR-LOBE SECRETION

With all these new findings and new ideas coming forward, it is obviously essential to reconsider the facts which sustain the conventional view that the neurohypophysis itself is a secretory organ. As the history of the subject shows (compare, for example, van Dyke 1936, with his 1939 review of the subject), recourse can hardly be made to histology for proof that the posterior lobe is a secretory organ. Nor can we take the fact

(e.g., Geiling 1935) that posterior-lobe hormones can be extracted from isolated pars nervosa tissue as indicating that the hormone is elaborated there—it might well have been produced, as the new theory suggests, in the hypothalamus. In view of this possibility, the only kind of evidence that could be taken as proof that the pars nervosa is itself a secretory structure would have to be derived from tissue-culture experiments. And even so it could be argued—if it turned out that cultures of posterior lobe do not produce hormone—that such a result was only to be expected in view of the fact that none is produced even by the posterior lobe in situ once it is released from hypothalamic control.

The evidence from tissue-culture experiments is far from convincing—in spite of the frequency with which it is cited. Geiling and Lewis (1935) prepared cultures of pars nervosa and intermedia taken from rats and mice, and allowed them to grow for up to fifty days. The pars nervosa tissue gave rise to an abundant growth of long, flat, radiating cells, and of neuroglia-like cells. The cultures were found to have both a pressor and melanophore-expanding action, but there is a suggestion, too, that the nutrient medium itself had a slight pressor effect.²⁰ A test for antidiuretic action was made with only one culture, and it gave no more than "some indication" of the presence of an active antidiuretic principle (Lewis 1938). What one does not learn from reports of experiments of this kind is: (a) how rigid the controls were; (b) how specific the tests were for posterior-lobe hormone²¹; and (c) whether such activity as was demonstrated in the culture was not due to the persistence of hormone that was there already (a point which applies regardless of the negative results of a few control cultures of connective tissue to which a solution of posterior-lobe hormone had been added).

Anderson and Haymaker's (1935) observations are equally indecisive. These authors found that there was no growth of pars nervosa elements in cultures of posterior-lobe explants taken from 8-day-old rats. The cultures were extracted after 6 days, and the melanophore-expanding principle—a product of the pars intermedia—was shown to have increased. This principle was also found in some cultures which were left for 9 or 12 days. No oxytocic hormone could be demonstrated, but some antidiuretic effect was observed, presumably in 6-day-old cultures, in three tests on dogs.

This seems to be the best evidence that can be cited about the secretory capacity of posterior-lobe explants. What little it indicates is far too inconclusive to provide any challenge to the idea that the so-called posterior-lobe hormones are, in fact, secreted by hypothalamic nuclei.

This new thesis also hardly conflicts with any of the facts—as opposed to interpretations—which Ranson and his colleagues disclosed in their classical series of researches on the cat and monkey. Both old and new theories agree that once the tractus hypophysius is interrupted, the distal part of the neurohypophysis atrophies and soon becomes free of hormone. According to Ranson's interpretation, the change is due to the interruption of a trophic and secretomotor innervation. According to the newer view, it is essentially due to the blocking of channels along which hormone flows. A more difficult issue to reconcile is the amount of retrograde degeneration that occurs in hypothalamic nuclei after division of the axons which form the tractus hypophysius. In agreement with earlier workers (e.g., Kary 1924, Lewy 1924), Ranson and his colleagues (Fisher et al. 1938) hold that all the cell bodies in the nuclei supraopticus and paraventricularis (particularly in the former)

20. It is not stated that the nutrient medium had no effect, but merely that it had no "appreciable effect on the blood-pressure."

21. On this point see van Dyke (1936); also Noble et al. (1950), Pickford (1952).

19. Abel (1924) was the first to show that extracts of the hypothalamus had pressor and oxytocic activity.

involute. Stutinsky (1951a), however, does not agree that this is so—he claims that a very large number of neurons remain functional. The difference, however, is mainly one of emphasis. Fisher, Ingram, and Ranson (1938) themselves point out that a fully developed diabetes insipidus will not occur unless the entire neurohypophysis, including the centre part of the tuber cinereum, is removed, and that “in general the intensity of the diabetes insipidus is proportional to the degree of interruption of the supraoptico-hypophysial tract.” This is in fair agreement with the neurosecretory view, according to which sufficient antidiuretic hormone will be released into the blood-stream to maintain the diuretic/antidiuretic process in balance, as long as a critical amount of the two relevant nuclei is intact.

POSSIBLE CONTROL OF ANTERIOR LOBE BY POSTERIOR-LOBE HORMONE

One final question needs to be raised, even though it cannot be pursued in detail. Is there any evidence that posterior-lobe hormone—the hypothalamic “chemotransmitter” which has been revealed by all these post-war researches—can itself activate and control the many functions of the anterior lobe? The simple answer is: so far, none that stands up to close examination. For example, it is known (e.g., Nagareda and Gaunt 1951, Stutinsky et al. 1952) that strong and non-physiological doses of posterior-lobe hormone can stimulate the release of A.C.T.H. But much more will need to be revealed about this response (for example, its differentiation from a reaction due to the stress of the experiment) before we shall be in a position to evaluate it properly.

The anatomical facts that bear on the point also need close scrutiny. The median eminence in birds and in most mammals that have been studied is differentiated into an inner ependymal zone; a middle coarse-fibre layer; and an outer so-called glandular layer which is devoid of cells and which essentially consists of very fine nerve-fibres, believed to be dendrites or possibly axons of the nuclei tuberis infundibularis, set in an interstitial “colloid” (e.g., see Nowakowski 1951, 1952, and Wingstrand 1951a and b). The central fibre layer consists of the axons of the nuclei supraopticus and paraventricularis, which terminate at all levels in the stalk and infundibular process of the posterior lobe. Only this layer stains electively with chrome-alum-haematoxylin, the outer glandular layer, which is in contact with the pars tuberalis and the primary capillary loops of the pituitary-portal vessels, being apparently devoid of the Gomori-positive granules which mark the flow of the posterior-lobe hormones. In some mammalian species the outer layer is reduced in thickness, and, according to Hanström (1953), is partly represented by tissue of corresponding histological appearance around the capillaries deeper in the eminentia. This occurs in certain Hyracoidea, Artiodactyla and Primates—including the orang-utan.

Gomori-positive granules have been demonstrated in the vessels of the posterior lobe (Hanström 1952a and b), but under normal conditions they apparently do not occur in those of the anterior lobe.²² Again, the very fine fibres which have been diagnosed as nerve-fibres in the outer “glandular” zone have not been proved—at any rate in mammals²³—to come from the nucleus tuberis infundibu-

laris, and opposing views are held about their nature (cf. Nowakowski 1952, Hanström 1952b). Indeed, Palay (1953) failed to confirm that they were present at all in the rhesus monkey. He believes that the only nerve-fibres in the median eminence are those of the middle zone which, while they may approach the radicles of the pituitary-portal veins, never establish contact with them. Palay's view is that the vessels and nerves of the median eminence are similarly arranged in man, the cat, rabbit, guineapig, and rat (but not in the mouse), where fibres have been described as terminating on the vessels.²⁴

Histological study thus provides no indication that “Gomori substance” normally can or does enter the pars distalis, and it cannot, therefore, be taken to support the view that posterior-lobe hormone activates the anterior lobe. If there is a hypothalamic chemotransmitter, which controls this lobe, its source would, by exclusion, have to be the very fine “nerve-fibres” of the outer glandular zone—in those species where they exist. There is no cytochemical evidence that this is so,²⁵ nor has a substance specific to this region alone been recognised pharmacologically. In short, it is not quite clear on what grounds, other than the presence of interstitial colloid, the outer zone of the median eminence has been called “glandular”—unless it merits this name because of its close anatomical association with the pars tuberalis of the adenohypophysis.

Conclusion

We can only conclude, therefore, that if the posterior-lobe hormones control the varied and varying functions of the anterior, this is not yet apparent from the evidence before us. In drawing our parallel between the present and the past, we must rest satisfied for the moment with the fact that modern science has not only established that the infundibular region of the brain does produce a vital essence, but that it has also apparently discovered the pathway by which this essence moves down the pituitary stalk into the posterior lobe of the gland. Swedenborg's “genuine or fresh” infundibular spirit and Luschka's fine tubes have thus taken real shape and meaning. So too, have the axial-stalk vessels discovered by Lieutaud two hundred years ago. But what principle, if any, these convey, and how the “reflex” responses of the anterior lobe are controlled, are two problems which still challenge our curiosity—as they have done for many years past.

22. According to Stutinsky (1951a), when the stalk is cut and the normal flow of the granules affected, they may pile up in the outer “glandular” zone of the median eminence, and may even get into the primary capillary loops, as well as into the third ventricle.
23. Wingstrand has provided convincing histological evidence that they do so in birds. The nucleus tuberis infundibularis, which is said to be “Gomori-negative,” is distinct from the nucleus mammillo-infundibularis, which is said to be “Gomori-positive” (Smith 1951). In man both are described as forming part of the “lateral hypothalamic area” (Clark 1936).
24. Both Wingstrand and Benoit refer to nerve-fibres forming loops in the outer glandular zone, and approaching the primary capillary net of the portal vessels. Wingstrand, however, has never observed the fibres terminating on the vessels.
25. As already noted, an interstitial—as opposed to intra-axonal—colloid is present in the external glandular layer, but whether this is evidence of “glandular” is debatable.

TRIGEMINAL NEURALGIA PATHOLOGY AND TREATMENT

G. F. ROWBOTHAM
B.Sc. Manc., F.R.C.S.

SURGEON-IN-CHARGE, NEUROLOGICAL DEPARTMENT, NEWCASTLE GENERAL HOSPITAL; NEUROLOGICAL SURGEON, ROYAL VICTORIA INFIRMARY, NEWCASTLE UPON TYNE

PAINS in the face may result from lesions that are demonstrable by simple examination, by special investigation, or by dissection at necropsy. On the other hand, there are varieties of continuous or periodic facial pain for which no cause can be found either in life or after death.

Trigeminal neuralgia (Fothergill's disease, prosopalgia, facial tic, or tic douloureux) is one of those maladies for which no definite pathological basis has been discovered. In diseases where a physical lesion exists, removal of the lesion usually gives relief; but the problem in conditions such as trigeminal neuralgia is entirely different, and surgical treatment consists in division at some peripheral or central level of the pain pathways concerned.

Characteristics of the Pain

The essential feature of major trigeminal neuralgia is that the pain is spasmodic and not continuous. It occurs in lightning flashes which usually are only momentary but occasionally last for as long as a few minutes. The pain is confined to the distribution of the trigeminal nerve. When the facial muscles on the affected side go into spasm during an attack, this spasm is more in the nature of "flickering" than of true contraction. In severe cases the pain may recur many times a day. Commonly there are periods of freedom, but eventual recurrence is usual—possibly after an interval of years.

The pain is initiated by any slight movement of the face, as in chewing or speaking; and a light touch—say to the side of the nose—may bring on an attack. In an attack the patient remains completely still, often holding a hand near his face, not touching it but as if for protection against any further stimulus. This unwillingness to touch the painful area is of great diagnostic significance, since in other types of facial pain the patient usually rubs his face in an attempt to get relief. The pain commonly originates from a localised area, known as the trigger-point. At the end of an attack the patient is completely free from pain, although there is always great apprehension of a further attack.

Neuropathology

No definite pathological change in the trigeminal pathways or the contiguous tissues has been found to account for the pain of trigeminal neuralgia. Organic lesions, such as acoustic neuromata and aneurysms, can of course cause pain indistinguishable from that of trigeminal neuralgia but in most cases no such lesion is present.

Harris (1926, 1937) suggested that the pain of trigeminal neuralgia is of peripheral origin, because in an untreated case there is never any objective loss of sensation or evidence of trophic disturbance. He argued that if the pain were central in origin, peripheral nerve block

or neurectomy would be unlikely to give relief. In many of his cases the pain had followed difficult dental manipulations; and, because trigeminal neuralgia usually affects the lower two divisions of the trigeminal nerve (that is, the divisions that supply the teeth), he argued that the pain might be due to septic filamentous neuritis secondary to dental sepsis. He drew attention to the prevalence of right-sided neuralgia, and suggested this was possibly due to the fact that, in the right-handed majority, the teeth in the left side of the mouth were more thoroughly brushed than those on the right, with the result that sepsis was more frequent on the right side.

Dandy (1934), from his experience of operations on the cerebellopontine angle, believed that trigeminal neuralgia was due, in many cases, to irritation of the nerve by a tumour, by an aneurysm, or by loops of the branches of the basilar artery, particularly the superior cerebellar artery.

Frazier et al. (1937) concluded that the thalamocortical mechanisms were at fault and that the severe and overwhelming quality of the pain in trigeminal neuralgia was due to misinterpretation and over-estimation at the higher neural centres of a normal peripheral message. To substantiate this hypothesis, Lewy and Grant (1938) described 6 cases of trigeminal neuralgia in which necropsy revealed gross structural changes in the thalamocortical connections. They pointed out that trigeminal neuralgia arises largely at an age when degeneration of the brain is most likely; they further emphasised the absence of structural changes in the peripheral mechanisms, though Lewy and Frazier (1935) thought that the threshold for pain in the peripheral mechanisms was below normal. The high incidence of trigeminal neuralgia in patients with disseminated sclerosis may seem to support this hypothesis. On the other hand, most workers argue that cerebral degenerative changes, as judged by the clinical findings, are rare in trigeminal neuralgia.

In 5 cases of trigeminal neuralgia in which I did air-encephalography, there was no evidence of ventricular distortion or enlargement to suggest a thalamocortical lesion. In most cases there is not a single neurological sign to point to the presence of an extrapyramidal or pyramidal lesion. Moreover, on the hypothesis of imbalance of the thalamocortical mechanisms, it is difficult to explain the remissions that occur so commonly. Possibly, however, a neural message could be misinterpreted centrally without any evident structural change being present.

Wyburn-Mason (1953) implied that, as a result of distortion of the neural pathways of the first and second cervical nerve-roots, the patterns of the pain plexuses of the skin of the face became abnormal. Weddell and his associates, in a series of important papers (Weddell 1941, Weddell and Sinclair 1947, Weddell et al. 1948), have shown that in the skin pain fibres from several sources are interwoven, and only when this complex structure is intact is a pin-prick registered in the normal way. When, because of nerve damage, the normal neural pattern in the skin is replaced by a simpler meshwork, a pin-prick is registered protopathically. This possibility of alteration in the pain meshworks of the skin interested me many years ago, and in 3 instances the trigger-points of the skin were excised and were examined by the late Prof. A. F. Bernard Shaw; on no occasion were changes found in the pattern of the skin-pain plexuses.

Another possibility is that the pain may arise from excessive spasm or dilatation of a blood-vessel, the impulses merely being transmitted by the trigeminal pathways.

PERSONAL OBSERVATIONS

Of 250 personal cases 176 were treated by operation: the trigeminal pathways were approached extradurally

TABLE I—DISTRIBUTION BY AGE AND SEX OF 250 CASES OF TRIGEMINAL NEURALGIA

Age (years)	No. of cases	
	Male	Female
20-29	1	1
30-39	6	12
40-49	15	17
50-59	24	29
60-69	36	60
70-79	11	34
80-89	—	3
90—	—	1
—	93	157

via the middle fossa. Although the middle meningeal artery varied in size, neither the artery itself nor its larger branches were ever found to be in such a position that they might beat against the third or second divisions of the nerve or against the ganglion. On one occasion only was a large artery discovered passing through the foramen ovale with the third division of the nerve. Usually large veins run along the margins of the divisions as they enter the ganglion; and, though these are often found congested at operation, it is doubtful whether they ever produce pain. On no occasion was there evidence of an angioma, either about the ganglion itself or along the territories of the second and third divisions. Sometimes the dura mater was thick, sometimes thin; sometimes it stripped easily from the bone, and sometimes it was densely adherent to the periphery of the middle fossa. Sometimes it would strip easily from the second and third divisions and from the ganglion itself; sometimes it was so adherent it had to be reflected by means of sharp dissection. In my opinion, it is not in the dural variations that the source of trigeminal neuralgia will be found. Obvious narrowing of the foramen ovale or foramen rotundum and constriction of the relative divisions was never found.

Thus no constant change was discovered that might account for trigeminal neuralgia in this series.

Histological Findings

Lengths of the third and second divisions, pieces of the ganglion, and lengths of the posterior root were removed and sectioned, care being taken to avoid artefacts. Of 15 specimens none was found to show any lesion. These examinations were also carried out by Professor Shaw.

Pieces of skin forming the trigger-points of the pain at the corner of the nose were excised as an ellipse in 3 patients. The pain plexuses in the skin were examined by the method of Weddell (1941); in none of these 3 instances was there any obvious alteration in the pain-plexus pattern, but Professor Shaw and I considered that there was an increase in fibrous tissue. As large nerve-roots pass, for example, along or through muscle-planes, they are surrounded by the equivalent of a synovial tunnel, which ensures that the nerve can slide freely without traction or distortion whenever the limb is made to move. Perineural adhesions resulting from inflammation will prevent the free slide of a large nerve along a neighbouring tissue and give rise to perineuritis

TABLE II—SITE OF PAIN IN 250 CASES OF TRIGEMINAL NEURALGIA, ACCORDING TO AFFECTED DIVISION OF FIFTH CRANIAL NERVE

Division affected	No. of cases	Division affected	No. of cases

and to pain. My suggestion is that a similar condition occurs about the peripheral filaments of the nerves, producing what could be termed perifilamentous adhesive neuritis. This differs from Harris's original hypothesis only in that he regarded the peripheral lesion as a mild interstitial neuritis. In my opinion, most of the evidence favours the conclusion that the lesion is essentially peripheral.

These histological experiments should be repeated, because trigeminal neuralgia can perhaps best be explained on Weddell's hypothesis.

Material

The age and sex distribution of 250 consecutive personal cases of trigeminal neuralgia is shown in table I. In 82 cases the left side was involved and in 163 cases the right side, while in 5 involvement was bilateral. The sites of the pain are shown in table II.

The disorder had been present for up to 3 months in 13 cases, for 4-6 months in 15 cases, for 7-12 months in 32 cases, for 13 months to 5 years in 95 cases, for 6-10 years in 39 cases, for 11-20 years in 25 cases, for 21-30 years in 4 cases, and for 31-40 years in 1 case; in 26 cases the duration was not recorded. The shortest history was 1 week, and the longest over 40 years.

Blood-pressure

In 64 cases there was no record of the blood-pressure. Of the remaining 186 cases, there was hypertension in 96 (51.6%) (see table III). Patients were classified as

TABLE III—DISTRIBUTION BY AGE AND SEX OF 96 CASES OF HYPERTENSION IN PATIENTS WITH TRIGEMINAL NEURALGIA

Age (years)	No. of cases	
	Male	Female
20-29	1	1
30-39	—	—
40-49	5	4
50-59	6	14
60-69	17	25
70-79	4	18
80-89	—	1
90—	—	—
—	33	63

hypertensive if the diastolic blood-pressure was 100 mm. Hg or more (see table III). It is very doubtful whether hypertension per se is a significant factor in the production of trigeminal neuralgia; many people above the age of 60 have hypertension without suffering also from trigeminal neuralgia.

Surgical Relief

Since trigeminal neuralgia is not caused by any lesion that is otherwise injurious to the patient, the only object of operation is to relieve pain. Moreover, the pain does not become intractable or incurable if surgical treatment is withheld or delayed. After root section regeneration of the trigeminal pathways is impossible, and after destruction of the ganglion it is unlikely; so relief obtained by root section or alcohol ganglion block is likely to be permanent. On the other hand, resection or alcohol block of the trigeminal pathways distal to the ganglion may give only temporary relief.

Division of the trigeminal pathways causes numbness in the territory of the face concerned, and numbness is a positive sensation carrying with it a disagreeable feeling of cold, stiffness, and swelling. Should the pain be unrelieved by destruction of a trigeminal pathway, the patient's burden is increased by this added disagreeable sensation. Therefore unless there is a definite probability that trigeminal section will result in relief, this manoeuvre should not be undertaken.

I believe that it is wrong, in the interests of permanent cure, to render the whole of the face numb when only

TABLE IV—TREATMENT OF 250 CASES OF TRIGEMINAL NEURALGIA

Initial treatment	No. of cases	Subsequent treatment
Injection :		
Gasserian ganglion	47	— Ganglion injection in 6 cases
2nd division	1	
3rd division	6	
3rd division and infra-orbital nerve ..	1	
Infra-orbital nerve	17	
Supra-orbital nerve	1	
Infra-orbital and supra-orbital nerves	1	
Total	74	
Operation :		
Complete root section	15	— Complete section in 3 root cases
Fractional root section	113	
Intracranial 2nd-division neurectomy	38	Complete section in 1 root case
Avulsion of supra-orbital nerve ..	1	—
Avulsion of infra-orbital nerve ..	9	—
Total	176	

one area is painful; in my experience, it is not true that a patient's morale is undermined by fear of a possible return of the pain with consequent need for further operation. On the contrary, I have found that most patients prefer to have as little done as will give immediate relief from pain for a reasonable length of time, and that if further operation does become necessary they show no undue apprehension.

In this series, of the 250 patients, 34 had pain in all divisions and 172 had no pain in division 1 (see table II). Among these 172 the disorder had been present for several years, and therefore spread of pain to division 1 is by no means inevitable even after a long period. As table IV shows, complete root section or ganglion block is not necessarily inevitable following incomplete operations, such as fractional root section, peripheral neurectomy, or peripheral nerve block.

Controlled fractional block of the ganglion is not technically possible by injection; so if the ganglion is injected in all cases, whether or not the first division is affected, the danger of paralytic interstitial keratitis must be greater than with fractional root section, by which the ophthalmic fibres can be spared in suitable cases.

Where the first division is affected, the advantage of ganglion injection over complete root section is that it avoids the danger of facial paralysis. Regarding danger to life, I have been operating on the trigeminal pathways by the extradural middle fossa approach for more than twenty years without a single death. Operation is very much easier for the patient, because it eliminates the usually very distressing experience of having a needle plunged into the face. In this series there is no doubt that the patients treated by operation were much more grateful than those treated by injection.

The advantages of fractional root section in suitable cases are outstanding: the cornea can be left sensitive, the numb area confined to the affected divisions, and the motor nerve spared. In this series there was no instance of permanent facial paralysis after complete or fractional root section. In my opinion, fractional root section is the method of choice in all cases where the first division is not affected. Where the first division is affected, alcohol injection and root section are equally efficient. Root section is a precise procedure, and I have never yet failed to section the root when this has been necessary; even the most expert, however, can fail to introduce a needle into the ganglion.

There is now a tendency in some centres to approach the posterior root via the middle fossa intradurally. The advantage of this method is the avoidance of facial paralysis and of bleeding into the middle ear. The intradural approach, though now safe in most hands,

must, by its very nature, carry a greater risk to life than the extradural approach. The actual section of the root fibres is equally precise by either method.

Intracranial extradural neurectomy of the second division is a most valuable procedure in suitable cases. By this means, the territory of only the maxillary division of the face need be denervated when the pain is confined to this area. Occasionally, when doing a fractional root section I also do neurectomy of the second division when it is essential that no fibres of this division be spared but no fibres of the first division sacrificed. With neurectomy of the second division alone, there is no danger of paralytic interstitial keratitis or of facial paralysis.

Extracranial alcohol blocks of the second and third divisions are safe and produce local denervation only. Their chief disadvantage is that the relief is temporary, lasting at most two or three years.

Avulsion of the supra-orbital or infra-orbital nerve is not a serious undertaking and is worth trying in old people when the trigger-point seems to be in one of these areas. The relief gained, however, is merely temporary.

Although procaine injection into the gasserian ganglion has not been applied in this series, it will often bring to an end a bout of trigeminal neuralgia and provide a period of remission.

Lastly, I would emphasise again that where the ophthalmic division is unaffected, fractional root section by the middle fossa extradural approach is, in my opinion, the treatment of choice.

Summary

A series of 250 cases of trigeminal neuralgia is analysed.

On the basis of histological studies it is suggested that the lesion is essentially peripheral, consisting in "perifilamentous adhesive neuritis."

Relief of the pain by surgical treatment is discussed.

I should like to take this opportunity of thanking Prof. F. J. Nattrass, Dr. W. Ritchie Russell, and Dr. R. Whitehead for their helpful criticisms in the preparation of this paper.

ANÆSTHETIC EXPLOSIONS PREVENTION BY WITHDRAWAL METHOD

JOHN BULLOUGH

M.B. Lond., D.A.

CONSULTANT ANÆSTHETIST, DARTFORD GROUP OF HOSPITALS,
KENT

THE causes of anæsthetic explosions and the current methods for their prevention in Great Britain have been described by Lowe (1950) and Hadfield (1952). In the U.S.A. more elaborate precautions are taken owing to the greater danger of static sparks and the use of ethylene. Electrostatic hazards have been discussed by Bulgin et al. (1949), Magee and Braeken (1952), and Roberts and Hewer (1953).

Whenever explosive gases or vapours are in use, there is always a risk of explosion, be it remote, since the possibility of their being ignited by a static spark cannot be entirely ruled out. There are occasions when the use of an explosive agent (diethyl ether in particular) is highly desirable in the presence of a known source of ignition—e.g., diathermy—and many anæsthetists finding themselves in this position have their own methods of minimising the risk of explosion.

Fig. 1.—T-junction with tap.

A serious type of anæsthetic explosion, often fatal to the patient, is that which happens when a collection of gases in the room is ignited at some distance away from the anæsthetic apparatus; a flame travels across the room and "lights back" through the leak-point in the apparatus; the gases inside the apparatus and the patient's air-passages then explode. The method about to be described prevents this type of explosion.

Withdrawal Method

In the ordinary way explosive gas mixtures are allowed to escape through expiratory valves or other leak-points from the anæsthetic apparatus into the atmosphere of the room in which the anæsthetic is being administered.

By the withdrawal method the gases are not allowed to enter the atmosphere of the room; they are withdrawn out of the room through a pipe from the apparatus. This is achieved quite simply by the use of a T-junction, which is plugged into the anæsthetic circuit, the gases being led away from the junction through a length of rubber tubing ("withdrawal tubing") connected to it. The withdrawal tubing leads away through a door or a window or through the floor (see below) to a safe place.

T-junction (fig. 1).—The horizontal limb has a male connection at one end and a female connection at the other end; it plugs into, and makes continuity with, any part of an anæsthetic circuit with standard connections. The vertical limb is a tube of 1/2 in. internal diameter and can be shut off from the horizontal limb

Fig. 2.—T-junction in use with semi-closed ("semi-T-piece") anæsthesia. Valve unit could be removed altogether, if desired.

by a tap. 1/2 in. rubber tubing is connected to the vertical limb and may be of any length, since only the very slightest resistance (equal to a pressure of less than 0.5 cm. of water) is offered to the escape of gases along this tubing.

Clinical Use

"SEMI-CLOSED" CIRCUIT

Fig. 2 shows the method in use with a continuous-flow semi-closed circuit. The T-junction may be interposed between the valve-mount and the endotracheal adapter, or angle-mount to face-piece. When the tap of the T-junction is open, gases will pass along the withdrawal tubing rather than through the expiratory valve, there being more resistance in the latter; the reservoir bag collapses until almost empty.

If positive pressure is required for artificial respiration, the expiratory valve is first screwed down and the tap

Fig. 3.—Withdrawal method in use with circle absorber, explosive gases being led away through floor.

adjusted, in much the same way as an expiratory valve, to increase the pressure in the circuit.

If the patient is breathing spontaneously, an anæsthetic administered in this way is a cross between a semi-closed circuit and my T-piece technique (Bullough 1952). I call this "semi-T-piece anæsthesia."

The flow-rates of gases, &c., are exactly as for semi-closed anæsthesia or my T-piece technique.

CARBON-DIOXIDE ABSORPTION CIRCUITS

"Closed Circle"

When a "closed" circuit is in use with "basal" oxygen, plus ether or cyclopropane, and the apparatus is gastight, it will usually be found that the reservoir bag becomes distended periodically and some gases must be allowed to escape. This is because, almost invariably, for various reasons, more gases are run into the circuit than the patient can absorb. Conversely, if the bag does not become distended, it is highly probable that there is a considerable leak in the circuit.

Clearly the "closed" circuit cannot be relied on entirely to eliminate ignition of gases outside the apparatus.

First, all expiratory valves, &c., are securely shut off; the T-junction is plugged into the expiratory port

of the absorption unit (fig. 3) and the hoses connected to the T-junction; the tap is turned off. Whenever the reservoir bag becomes distended the tap is opened, the bag is squeezed until half-empty, and the tap is closed again. The excess gases pass away along the withdrawal tubing out of the room.

Fig. 4—To-and-fro absorption: withdrawal of explosive gases by use of tap on bag.

Fig. 5—To-and-fro absorption: withdrawal of explosive gases by use of T-junction.

Circle Absorption with Intentional Leak

This is a common technique, nitrous oxide and oxygen being the basic mixture, with total gas-flows of 1-5 litres a minute. If ether or cyclopropane is added, the administration may be managed in the same way as for a "closed" circuit when low gas-flows are used. If flows of more than 3 litres a minute are used, the tap on the T-junction may be adjusted to allow a continuous leak at any desired pressure.

If the patient is breathing spontaneously and the junction is placed between the patient and the absorber (fig. 3), some "rebreathing" can take place along the expiratory hoses. Owing to the design of the junction, however, this is very slight, provided the gravity valves are working freely. In addition, a high flow of fresh gases prevents any appreciable accumulation of carbon dioxide. "Rebreathing" will not take place if artificial respiration is in progress, or if the junction is placed between the absorber and the bag, as is easily arranged on other types of apparatus, or when a bag is used in place of the concertina on the type illustrated.

To-and-fro Absorption

Figs. 4 and 5 show how this method may be used during to-and-fro absorption. A small tap (fig. 4), formerly used for running gases into this type of bag, is now used to lead gases away. Alternatively, a T-junction (fig. 5), with unions of a suitable size, is interposed between the bag and the canister.

Disposal of Gases

The gases may be led away through any length of withdrawal tubing through a door or a window, to a safe place, preferably out of human reach, where they will not be ignited by cigarettes, &c.

Fig. 6—Disposal of explosive gases through pipe under floor to outside of building.

A more convenient method is to lead the gases through a hole in the floor placed near the head of the operating-table (fig. 3). This has been done at hospitals in the Dartford group by installing a metal pipe which leads through the floor to the outer wall of the building, and up this wall out of human reach (fig. 6). (Back-pressure in the pipe is negligible, less than 1 cm. of water.)

A perforated box or cage surrounds the end of the pipe as an additional safeguard against cigarette ends, and a warning notice is placed on the cage. It is hoped to find a gauze, like Davy gauze, which will prevent ignition and "lighting back" of emerging gases.

Discussion

The safety of this method depends on the anaesthetic apparatus, and the junction between apparatus and patient, being leakproof at the pressure at which the anaesthetic is being administered.

A great deal of the anaesthetic apparatus at present available in this country was designed before the risk of explosion had become what it is today. Electrical apparatus is now in almost constant use; techniques involving artificial respiration, and therefore high pressure in the apparatus, are also the rule rather than the exception in many operating-theatres.

In the apparatus illustrated in fig. 3 there are a dozen places where leakage can take place, excluding the rubber parts. Such an apparatus is difficult to keep gastight, and one is inevitably led to the conclusion that new apparatus should be designed to remain gastight under present methods of usage.

A gastight junction to the patient can fortunately be achieved with a cuffed endotracheal tube. If rupture of this cuff would be highly dangerous, a second cuff could be applied to the tube. Face-masks with inflatable rims are available which will form a gastight junction to moderate pressure in a high percentage of patients.

During artificial ventilation of the lungs, pressures in the circuit of 20 cm. of water are common and pressures of 40 cm. of water or more are not uncommon; in some circumstances far higher pressures are used for short periods. Clearly leakage from the circuit is far more likely to take place during artificial respiration than when the patient breathes spontaneously.

When the patient is breathing spontaneously, the pressure inside any circuit need not rise above 4 cm. of water. When the semi-T-piece method is used, the pressure will be less than 1 cm. of water, at which pressure leakage is quite easily prevented in present-day apparatus. I consider that this technique can be safely used with explosive anaesthetics in the same room as a known source of ignition, and have so used it for the last three years.

If this method is adopted as an additional safeguard against anaesthetic explosions, I suggest that, when pipes are laid to carry anaesthetic gases into an operating-theatre, an additional pipe be laid to carry them out again.

Quite apart from preventing ignition of anaesthetic gases, this method relieves all operating-theatre personnel from the necessity of breathing noxious anaesthetic gases and vapours emanating from the anaesthetic machine.

Summary

A simple method of preventing ignition of anaesthetic gas mixtures in operating-theatres, &c., is described: the withdrawal method.

The gases are prevented from entering the atmosphere of the theatre.

A T-junction, with a tap, is plugged into an anaesthetic circuit; a pipe attached to this conveys gases from the theatre to a safe place outside.

There is a need for anaesthetic apparatus of a new design, easily kept gastight to the pressure used in

clinical anaesthesia today. Only when the patient is breathing spontaneously can leakage from apparatus at present available be easily prevented.

Operating-theatre personnel are relieved from breathing anaesthetic gases by the withdrawal method.

I wish to thank Dr. M. Mitman, Dr. R. G. Henderson, C.B.E., and Dr. T. S. Cochrane, superintendents of the hospitals in the Dartford Group, for their interest in this method and for its installation in the operating-theatres in the Group; the hospital engineers for installing the apparatus to my specification; the British Oxygen Company for assistance in developing the method and for making the T-junctions; and Messrs. Woods & Porter, West Hill, Dartford, for the photographs. The T-junction may be obtained from Messrs. Charles King Ltd.

ALTHOUGH the clinical tests for urinary ketones are essentially qualitative, it is customary for clinicians to give them a quantitative significance based on certain characteristics, such as the intensity of the colour reaction and the rapidity of development of a colour, or by comparing the results of tests of different sensitivities. The usual tests vary so much in technique and interpretation that it is difficult to compare the results of different workers, especially when + symbols are used.

Friedemann et al. (1946) have reviewed the many ways in which the nitroprusside reaction may be used for detecting ketone bodies, and have drawn attention to the variety of methods and sensitivities reported.

Some workers state that the colour given by the nitroprusside reaction is due mainly to the presence of acetone (King 1951, Stanley 1943), whereas others state that it is due to both acetone and aceto-acetic acid (Harrison 1947). All workers agree that β -hydroxybutyric acid gives no reaction with sodium nitroprusside.

Few textbooks adequately present either Rothera's (1908) or Gerhardt's (1865) test.

Describing the Rothera test Todd et al. (1953), Lawrence (1950), and Harrison (1947) do not indicate that the urine must be saturated with ammonium sulphate to give the maximal sensitivity.

Bayliss (1950) adds 2 or 3 drops of a "concentrated" sodium nitroprusside solution, whereas King (1951) adds 8-10 drops of a 0.25% solution in 1% nitric acid.

The time allowed for the colour reaction to develop before its intensity is read varies from 1 to 30 minutes (Fearon 1946, Haler 1951, Lawrence 1950), or is not mentioned at all (Carter and Thompson 1953, Hawk et al. 1947).

Descriptions of Gerhardt's ferric-chloride test are also at variance. The strength and quantity of ferric-chloride solution used is often omitted. No workers agree about the time of boiling the urine to distinguish the colour given by aceto-acetic acid from that given by non-ketone substances, only one of them emphasising that the boiling should be prolonged (Hutchison and Hunter 1951).

It is therefore not surprising that clinicians do not usually relate the results of the tests with actual concentrations of ketone bodies present in the urine. It follows that the clinical tests for urinary ketones are of limited value in following the progress of a patient in ketosis. We report here studies of the Rothera nitroprusside and Gerhardt ferric-chloride tests, and include observations on a recently developed "nitroprusside tablet."† The object is to assess the significance of these tests so as to provide a more precise interpretation than has been possible hitherto. The relative merits of the tests for routine use were also studied.

Methods

Since the urine of patients with ketosis was not always available when required for study, it was necessary to add ketone bodies to normal urine. Preliminary experiments indicated that urines to which known concentrations of acetone and aceto-acetic acid had been added gave reactions of the same colour and intensity as those given by similar concentrations found in the urine of ketotic diabetic patients. To determine the relative proportions of acetone and aceto-acetic acid in the urine of ketotic patients, estimations of the individual ketone bodies were made by the method of Thin and Robertson (1952) on specimens of urine giving positive results to Rothera tests.

Stock solutions were made from aceto-acetic acid prepared by the method of T. E. Friedemann (personal communication) and from 'Analar' acetone and the concentrations determined (Thin and Robertson 1952). These solutions were added to normal urine to give concentrations of aceto-acetic acid ranging from 0 to 2000 mg. per 100 ml. in steps of 50 mg. per 100 ml. Further dilutions were made when necessary. The three tests studied were applied to these specimens of urine according to the methods described below. After preliminary trials each test was finally repeated twenty times on different occasions. In the Gerhardt ferric-chloride test the colour due to aceto-acetic acid is distinguished from that given by excreted products of certain drugs by boiling the urine and repeating the test. To establish the minimal time of boiling required to remove all the aceto-acetic acid present, 20 ml. aliquots of urine containing 25, 100, and 300 mg. of aceto-acetic acid per 100 ml. were boiled vigorously in a 50-ml. beaker for 5, 10, 15, and 20 minutes respectively, and the test was repeated after cooling and adjusting the volume to 20 ml.

TECHNIQUE OF TESTS

Rothera's Test

Of the various techniques reported that recommended by Friedemann et al. (1946) was found to be the most satisfactory. About 5 ml. of fresh urine is saturated with ammonium sulphate, and 10 drops of 2% sodium nitroprusside solution is added. The solution is well mixed, and 10 drops of concentrated ammonia (sp. gr. 0.880) is added. The purple colour due to the presence of acetone or of aceto-acetic acid is allowed to develop for 15 minutes. The reasons for selecting this particular technique are as follows:

(1) The urine must be saturated with ammonium sulphate to give the maximal sensitivity and to reduce the interference of non-ketone substances.

(2) A minimal quantity of sodium nitroprusside is used so as not to confuse a trace reaction with a colour due to excess reagent.

(3) The colour due to aceto-acetic acid reaches a maximal intensity in about 10 minutes, and that due to acetone in 20-30 minutes. After this time the colour begins to fade. Also, several sulphhydryl compounds give red colours which develop in a few seconds but fade within 3 or 4 minutes. By choosing a time of 15 minutes false positives are avoided and a maximal colour is obtained.

* In receipt of a scholarship grant from the Royal Free Hospital Endowment Fund.

† 'Acetest Reagent Tablet' manufactured by Miles Laboratories Ltd. (distributors Don S. Momand Ltd.).

Gerhardt's Test

Ferric-chloride solution 10% is added drop by drop to about 2 ml. of fresh urine. A precipitate due to phosphates usually forms but redissolves on further addition of ferric chloride. A reddish-brown colour may indicate the presence of aceto-acetic acid. If such a colour does develop, the urine must be boiled in an open vessel—e.g., a beaker—for at least 15 minutes to decompose the aceto-acetic acid to acetone, most of which boils off. If the boiled and cooled urine still gives a reaction similar to that of the unboiled urine, it is due to substances other than aceto-acetic acid.

TABLE I—CONCENTRATION OF KETONE BODIES IN URINE OF 21 KETOTIC DIABETIC PATIENTS

Acetone (mg. per 100 ml.)	Aceto-acetic acid (mg. per 100 ml.)	β -Hydroxy-butyric acid (mg. per 100 ml.)	Total ketones (mg. per 100 ml.)	Ratio of aceto-acetic acid to acetone
5.9	62.3	188.2	256.4	10.1

Mean ratio of aceto-acetic acid to acetone 9.4 ± 3.6 .

Nitroprusside-tablet Method

This tablet contains sodium nitroprusside, glycine, disodium phosphate, and lactose. The technique adopted for this test is that described by the manufacturers. A tablet is placed on a clean white surface, and one drop of urine is allowed to fall gently on to it. At the end of 30 seconds the purple colour which develops when the test is positive is compared with the three shades of colour on the scale provided with the tablets. When the test is negative, the tablet remains unchanged in colour except for a slight creaminess due to the colour of the urine. In common with all nitroprusside reactions for ketone bodies the colour will continue to develop for several minutes. For this reason the colour scale is designed for use at the end of 30 seconds.

TABLE II—SENSITIVITIES OF ROTHERA TEST TO ACETONE AND ACETO-ACETIC ACID ADDED SEPARATELY TO NORMAL URINE

Result	Acetone (mg. per 100 ml.)	Aceto-acetic acid (mg. per 100 ml.)
Trace	25	1
+	100	5
++	200	10
+++	300	15
++++	400	20

Results

The levels of the different ketone bodies occurring in the urine of a series of ketotic diabetic patients whose ketosis ranged in severity from mild to precomatose are presented in table I. The levels of β -hydroxybutyric acid are included, although this ketone cannot be detected by the clinical tests for ketonuria.

A deep purple, through which it was only just possible to see transmitted light, was given by a solution of 400 mg. of acetone per 100 ml. in urine with the Rothera test. This depth of colour was called +++++. A faint purple was given by 25 mg. of acetone per 100 ml. This

TABLE III—SENSITIVITY OF GERHARDT TEST TO ACETO-ACETIC ACID ADDED TO NORMAL URINE

Result	Aceto-acetic acid (mg. per 100 ml.)
Trace	25
+	50
++	100
+++	150
++++	200

was called a "trace." +, ++, and +++ reactions were assigned to proportionate levels between these extremes.

Solutions of aceto-acetic acid were found which gave colour reactions corresponding to the intensities of colour given by the acetone solutions mentioned above. The concentrations at each level for both acetone and aceto-acetic acid are shown in table II.

In determining the sensitivity of Gerhardt's ferric-chloride test the use of a standard solution of aceto-acetic acid was found to be undesirable, because its preparation was lengthy and its stability poor. It was therefore necessary to prepare an arbitrary standard which could be easily made up and did not deteriorate quickly. A solution of ethyl acetone dicarboxylate in urine gave a colour with ferric chloride which closely matched that given by the addition of ferric chloride to urine containing aceto-acetic acid. A 1% solution of ethyl acetone dicarboxylate in normal urine gave, on the addition of ferric chloride, a colour which corresponded to a strongly positive Gerhardt test such as is found in severe ketosis. This colour was called +++++, and on analysis was found to be equivalent to about 200 mg. of aceto-acetic acid per 100 ml. The lowest level at which a definite colour could be clearly detected without the aid of a control tube was about 25 mg. of aceto-acetic acid per 100 ml. As before, +, ++, and +++ were assigned to

TABLE IV—EFFECT OF BOILING URINE ON GERHARDT TEST

Duration of boiling (min.)	Aceto-acetic acid		
	25 mg. per 100 ml.	100 mg. per 100 ml.	300 mg. per 100 ml.
0	Trace	++	++++
5	$\frac{1}{2}$ -trace	Trace	+
10	Negative	Negative	Trace
15	Negative	Negative	Negative

reactions lying proportionately between these extremes (table III).

Table IV shows the result of boiling the urine containing various concentrations of aceto-acetic acid for different lengths of time. If only a little aceto-acetic acid is present, 10 minutes' boiling should be sufficient to remove it; but, if larger quantities are present, 15 minutes' boiling is necessary to ensure that no aceto-acetic acid remains.

The determination of the sensitivity of the nitroprusside tablets is much simplified by the use of the colour scale provided with the tablets. The concentrations of acetone and of aceto-acetic acid which corresponded most closely to each shade on the colour scale are shown in table V.

TABLE V—APPROXIMATE SENSITIVITIES OF NITROPRUSSIDE TABLETS TO ACETONE AND ACETO-ACETIC ACID ADDED SEPARATELY TO NORMAL URINE

Result	Acetone (mg. per 100 ml.)	Aceto-acetic acid (mg. per 100 ml.)
Detects	25	5
Trace	100	20
Moderate	250	40
Strongly positive	800	80

Discussion

Table I shows that there is usually about nine times as much aceto-acetic acid as acetone present in the freshly voided urine of ketotic patients, which is in agreement with Folin (1934), who found a ratio of 10 to 1. With the Rothera test aceto-acetic acid yields a colour about twenty times as intense as that of an equal concentration of acetone (table II). Therefore only about a two-hundredth of the colour produced is due to acetone. Even in severe ketosis levels of acetone greater than about 50 mg. per 100 ml. have not been observed. It follows that for practical purposes the Rothera test can be regarded as a test for aceto-acetic acid only.

Table II shows that a deep purple (++++) is given by 20 mg. of aceto-acetic acid per 100 ml. In our experience clinical signs of ketosis do not develop when the urine contains less than about 50 mg. of aceto-acetic acid per 100 ml. Owing to the extreme sensitivity of the Rothera test concentrations of this level and greater all give ++++ reactions; hence differing degrees of clinical ketosis cannot be distinguished by the test. However, when the concentration of aceto-acetic acid in urine is very low, it is possible to detect differences in the colour intensity by a standardised technique. Table II shows that 1 mg. of aceto-acetic acid per 100 ml. can be detected, but it is not clear at present whether the detection of such small amounts of ketone bodies in the urine is of any help in assessing a patient's clinical condition. It appears that, unless a very carefully standardised technique is used for the Rothera test, misleading results will be obtained. Such a technique takes at least 15 minutes.

The Gerhardt test is more useful clinically than Rothera's test because it is considerably less sensitive and covers a wider range of ketone levels (table III). Unfortunately it has a serious disadvantage in that several drugs in common use produce excretory substances which give a colour with ferric chloride similar to that given by aceto-acetic acid. It is fairly easy to distinguish the colour due to drugs from that due to aceto-acetic acid by boiling the urine and repeating the test. Table IV shows that 15 minutes' boiling in a beaker is essential to ensure that all the aceto-acetic acid is removed. Momentary boiling in a narrow test-tube, as is usually done, is inadequate. Any routine test involving this amount of time is obviously impractical for ward use. Thus it seems that both the Rothera and the Gerhardt tests are far from ideal for ward and clinic use. Though laboratories using standardised techniques may achieve satisfactory results, it is unreasonable to expect nurses to devote the time necessary for the proper performance of these tests.

Little advance has been made in urinary ketone tests since the introduction of Rothera's test in 1908 until the recent production of a tablet form of the nitroprusside reaction. The tablet method appears to overcome many of the objections to the previous tests. The sensitivity of the tablets to aceto-acetic acid is roughly intermediate between that of the Rothera test and that of the Gerhardt test (tables II, III, and V). By the use of this test detection of the lower levels of ketonuria, which are of doubtful significance, is avoided. Clinical trials on a large series of ketotic patients will be necessary to establish a more exact relationship between the ketone content of the urine and the patients' condition. Clinical symptoms of ketosis are not evident when the ketone test shows less than a "trace" reaction by this method. As with the Rothera test, practically no colour is contributed by the acetone present, even in the urine of severely ketotic patients.

The advantages of the tablet method for general use are unquestionable. The tablet is stable and non-caustic, no obnoxious fumes or ammonia are evolved, and no other reagents or apparatus are required. It provides

the clinician with a standardised procedure which is so simple that variations are unlikely. The nitroprusside reaction in this form is specific. The presence of blood-glucose, protein, creatinine, and the excreted products of commonly used drugs such as salicylates, phenazone, barbiturates, and phenol has no effect on the test. It is almost impossible to see a positive reaction with the older tests in a specimen which is grossly contaminated with blood. When the tablet is used, such a small amount of urine is required that the reaction is neither masked nor influenced by the presence of blood.

A major consideration in the routine testing of urine is the large amount of time taken. In this respect the tablets effect a very considerable saving. The Rothera test, as usually done, takes about 5 minutes, and the Gerhardt test about 2 minutes when negative and 6 minutes when positive (this allows only 2 minutes for boiling, which is inadequate for removing large amounts of aceto-acetic acid). Since the tablet method takes less than a minute, about 4 minutes is saved on each Rothera test. There would be a further saving of about 5 minutes on each Gerhardt test. If both of the older tests were superseded by a tablet test, about 10 minutes would be saved on each examination of urine. Gray and Millar (1953) have claimed that with 100 specimens of urine to be tested for sugar 9 hours is saved by using a tablet method. It appears that about 16 working hours would be saved on 100 urine tests done by the nitroprusside-tablet method. The tablet methods for sugar and ketones may be used simultaneously within a minute.

In view of the great clinical importance of tests for urinary ketone bodies the Rothera and Gerhardt tests seem to be unsatisfactory in comparison with other biochemical tests, such as those for glucose. The tablet adaptation of the nitroprusside reaction, in addition to being simple, quick, and reliable, provides an indication of the degree of ketosis, and seems worthy of more extensive clinical trials. For the detection of minute traces of ketone bodies Rothera's test is the most sensitive.

It is realised that the level of ketonuria is not always a reliable indication of the degree of ketonæmia. A rapid and accurate method of estimating the plasma-ketone level is required. Further studies on this problem are in progress.

Summary

The sensitivities of the Rothera, Gerhardt, and nitroprusside-tablet methods for detecting urinary ketones are compared, and their suitability for clinical use is discussed.

The earlier tests have several disadvantages, such as the absence of a standardised technique, and the large amount of time involved when the tests are correctly made.

The need for a simple and quick clinical method for detecting urinary ketone bodies is largely met by the introduction of the nitroprusside tablet.

The quantitative levels of the individual ketone bodies in the urine of patients in different degrees of ketosis are presented.

We wish to thank Dr. Una Ledingham, F.R.C.P., for her support and for making available the facilities of the diabetic department. The work was aided by a grant from the Royal Free Hospital Endowment Fund.

POTENTIATION OF CORTISONE BY GLYCYRRHETINIC ACID

F. DUDLEY HART JOHN C. LEONARD
 M.D. Edin., F.R.C.P. M.D. Lond., M.R.C.P.
 ASSISTANT PHYSICIAN REGI-STRAR
 WESTMINSTER HOSPITAL, LONDON

WITH continuing restriction of supplies of cortisone in this country, any substance which might prolong or intensify its therapeutic action is worth investigating. Hitherto all efforts to produce such potentiation have failed; *p*-aminobenzoic acid, insulin, and other substances have not been proved useful in this respect. Some workers have found that gold therapy not only fails to increase cortisone action but actually reduces it—i.e., the two substances are antagonistic. When therefore Borst and his colleagues (1953) found that liquorice, in addition to a mineralocorticoid action, appeared to potentiate the action of cortisone in Addison's disease, we felt that a clinical trial in other conditions would be well worth while. Card et al. (1953) found in a case of Addison's disease that glycyrrhetic acid, which occurs in liquorice in the form of its glucuronide (glycyrrhizic acid), had effects on weight and electrolyte balance similar to those found after the administration of deoxycortone and cortisone. It seemed to us that this substance might be tried, in conjunction with small doses of cortisone, in cases of rheumatoid arthritis, to see whether this had any anti-inflammatory effect such as would be seen with larger doses of cortisone alone.

Methods

Eleven patients (six male, five female) were selected for study; their ages ranged from 39 to 65 years. Eight patients were treated in hospital, and these had a preliminary period of rest in bed. Most of the patients were also placed on a basic régime of physiotherapy. Each patient was then treated with cortisone. When the clinical condition was judged to be stationary inert lactose capsules were given in addition to cortisone for two days as a control; these capsules were identical with those containing glycyrrhetic acid. A course of glycyrrhetic acid 0.5 daily was then given, usually for five to seven days; during and after this course the dosage of cortisone was unaltered. The eleven patients received altogether fifteen such courses of glycyrrhetic acid.

Two methods of stabilising the patient on cortisone were followed:

1. In the first method, used eleven times, the patient was given small doses of cortisone (15–37.5 mg. daily) until the clinical condition became static, with symptoms and signs only suppressed in slight degree; glycyrrhetic acid was then added.

2. In the second method, used four times, larger doses of cortisone (37.5–100 mg. daily) were given until a remission was obtained; the dosage of cortisone was then progressively reduced until a slight relapse resulted; glycyrrhetic acid was then given without further adjustment of the dose of cortisone.

Assessment

A combination of subjective and objective criteria was used for assessing the progress of the patient. Subjective assessment was based on: (1) the patient's own estimation of the degree of pain and stiffness expressed as a percentage of the pain and stiffness present at the onset of the trial; (2) the number of tablets of aspirin needed each day to relieve pain; (3) the grip of each hand, as measured with a dynamometer; (4) tenderness, as estimated by the application of gradually increasing pressure by the observer.

The range of movements of various joints—usually the wrists—was measured when applicable. In addition the degree of swelling of the proximal interphalangeal joints was measured by the use of Wheatshaf rings; this has proved a reliable and sensitive method of measurement when used by the same observer (Hart and Clark 1951).

Results

On the whole, the results of the investigation were discouraging. In five patients the results were wholly negative; and in five others the results were probably negative, though certain unusual features were present. In only one patient was there any convincing evidence of potentiation of cortisone by glycyrrhetic acid.

This patient, a woman aged 51, had had rheumatoid arthritis for two years. She was admitted to Westminster

Findings in case of rheumatoid arthritis treated with glycyrrhetic acid.

The amount of pain and stiffness before starting the trial was estimated at 100%. Wrist movements, tenderness, grip, proximal interphalangeal joints swelling: "0" represents the state at the onset of the trial; "plus" figures represent improvement and "minus" figures deterioration. The measurements were appropriately standardised.

Hospital on June 13, 1953, and after three successive subjective and objective assessments at intervals of three days had given fairly constant readings, she was treated with 37.5 mg. of cortisone daily. Within a few days she had a satisfactory remission, confirmed by all the subjective and objective criteria. After twelve days the daily dosage of cortisone was reduced to 25 mg., and within twenty-four hours there was a partial relapse, confirmed by further measurements taken four days later. A course of glycyrrhetic acid was then given for seven days, with considerable improvement according to all methods of estimation (see figure). When the glycyrrhetic acid was stopped there was a further relapse. She was discharged on 25 mg. of cortisone daily, and attended the outpatient department once weekly. A further course of glycyrrhetic acid was then given, this time for three weeks. This immediately produced great symptomatic improvement, shown by the fact that the patient took no codeine tablets for seven consecutive days. Later there was objective improvement also. When the glycyrrhetic acid was stopped the objective improvement continued for several days, and then a further relapse occurred. The patient has since been satisfactorily maintained on 37.5 mg. of cortisone daily.

In several other patients there was a suggestion that glycyrrhetic acid might have a somewhat prolonged action; improvement occurred while a course of the drug was being given, but no relapse followed when the drug was stopped. It is more likely, however, that most of these inconstant improvements were due to the cumulative effect of rest in bed and small doses of cortisone. The absence of relapse when glycyrrhetic acid was stopped is strong presumptive evidence that this drug was not responsible for the improvement.

Discussion

It is notoriously difficult to assess impartially the progress of patients with rheumatoid arthritis. Spontaneous remissions and relapses are frequent, and seriously handicap the most objective observer. The patients respond so readily to suggestion that improved performance-tests often merely reflect the enthusiasm of the investigator. Despite these pitfalls, we believe that from this small series of cases of rheumatoid arthritis it is justifiable to conclude that glycyrrhetic acid has no distinct or constant potentiating action on cortisone. Possibly it may occasionally have a relatively mild effect—indecided, in the case described here it appeared to exert an effect equivalent to 12.5 mg. of cortisone. The inconstant improvement noted in several other patients supports this view, but such a feeble and inconstant action is unlikely to be of therapeutic value in treating rheumatoid arthritis.

Summary

Eleven patients with rheumatoid arthritis were treated with glycyrrhetic acid 0.5 g. daily, usually in courses lasting from five to seven days. The patients had previously been stabilised with symptoms only partly relieved on small doses of cortisone, which were continued during the administration of glycyrrhetic acid.

In only one patient was there any convincing improvement with relapse when the drug was stopped. In this case the drug had a potentiating action equivalent to 12.5 mg. of cortisone daily.

Any potentiating action by glycyrrhetic acid is too slight and inconstant to be of value in the treatment of rheumatoid arthritis.

We wish to thank Mr. William Mitchell, PH.D., of Messrs. Stafford Allen & Sons Ltd., for supplies of glycyrrhetic acid, and Prof. N. F. MacLagan, F.R.C.P., for his advice.

LIQUORICE EXTRACT IN ADDISON'S DISEASE SUCCESSFUL LONG-TERM THERAPY

ROWLAND J. CALVERT

M.B., B.Sc. Glasg., M.R.C.P., D.P.H.

SENIOR REGISTRAR, WHIPPS CROSS HOSPITAL, LONDON

THE deoxycortone-mimetic action of the juice and extract of liquorice has been demonstrated in normal persons (Borst 1950) and in patients with Addison's disease (Groen et al. 1951, Card et al. 1953, Parrish and Alpert 1953). The triterpene constituent, glycyrrhetic acid (Card et al. 1953, Pelser et al. 1953b), and its diglucuronate, glycyrrhizinic acid (Groen et al. 1951, 1952), have also proved effective in brief investigations in this disease. In the case described here liquorice extract was administered over a longer period.

Case-report

A housewife, aged 54, was admitted on April 19, 1952, with the classical features of Addison's disease. Weakness and loss of appetite and weight had been present for a year; brown pigmentation of the skin for nine months; and slowness of thinking for three months. Vomiting, faintness, and yawning had been frequent in the three weeks before admission. The history was negative regarding previous illnesses, operations, residence abroad, and family history of tuberculosis. The patient had a generalised "sun-tan," especially distinct over pressure areas, nipples, and axillæ; while black pigmented spots were present on the lips, tongue, and buccal cavity. The pulse-rate was 80 per min.; the blood-pressure was 85/55 mm. Hg, and there was no orthostatic hypotension.

Investigations

Table I summarises the biochemical and blood-pressure changes before and 1, 5, and 17 months after treatment with liquid extract of liquorice B.P. (Boots). When the daily dose was increased to 60 g. the blood-pressure, blood-urea, and serum-electrolyte values were restored to normal; and they have remained so, despite great reduction in the dose to prevent undesirable rises in blood-pressure. Serum-potassium and fasting blood-sugar values have fluctuated little, while results of blood-counts, hepatic tests, and urinalysis with microscopy have revealed no abnormality throughout.

The main pharmacological observations are summarised in table II, which shows the blood-pressure and general effect with, singly, liquorice extract (B), large doses of salt (C), and deoxycortone acetate (D), and a combination of liquorice extract and salt (E), compared with two separate-control phases (A) of one week without treatment. In each therapeutic phase (table II) the index of response adopted was the mean value of the four-hourly blood-pressure readings on the last day. This index was shown to be more reliable than body-weight in this patient. Each phase (B-E), with one exception, lasted one week or a multiple thereof. The exception was during combined liquorice and salt therapy (E₂), when, after two days on 60 g. of liquorice and 12 g. of salt daily, this treatment had to be terminated abruptly owing to premonitory pulmonary oedema with increased transverse diameter of the cardiac silhouette radiographically, associated with ankle oedema. Headache, which is a usual accompaniment of over-dosage with liquorice (F. E. Revers, personal communication), was not present. This situation had occurred previously after two weeks of combined treatment with 30 g. of liquorice extract and 12 g. of salt daily (E₁). It can be concluded from table II that 60 g. of extract of liquorice by mouth daily and the 5 mg. of deoxycortone by intramuscular injection daily were about equipotent and more than adequate to control the disorder; whereas 12 g. of supplementary salt alone proved insufficient for stabilisation after a three-week trial.

Two other interesting actions of liquorice extract were evident. A cumulative effect was observed immediately after each of the two abrupt cessations of treatment due to incipient pulmonary oedema (F); the blood-pressure failed to drop to normal until a further seven days and 10 days respectively had elapsed. This cumulative effect was also observed later when the blood-pressure remained normal for up to two days after abrupt cessation of therapy. Secondly, increased sensitivity in the response to liquorice therapy was observed. For instance, a smaller dose (30 g.) five months after admission

TABLE I—BLOOD-PRESSURE AND BIOCHEMICAL FINDINGS BEFORE AND 1, 5, AND 17 MONTHS AFTER START OF LIQUORICE EXTRACT THERAPY

Phase	Blood-pressure (mm. Hg)	Serum-electrolytes (mg. per 100 ml.)			Blood-urea (mg. per 100 ml.)	Fasting blood-sugar (mg. per 100 ml.)	Neutral 17-keto-steroids (mg. per diem in urine)	Kepler test "A" value	CO ₂ -combining power (vols. %)
		Na	Cl (as NaCl)	K					
Before treatment	85/85	275	445	31	60	98	0.48	4.8	..
1 month later (60 g. ext. glycyrrh. liq. daily) ..	135/80	345	579	17	29	95	62
After further 4 months (30 g. ext. glycyrrh. liq. daily) ..	130/80	325	555	18	34	100	0.62	4.5	63
After further year (4½ g. ext. glycyrrh. liq. daily) ..	125/80	315	573	19	35	96	0.76	9.2	60

(after completion of the pharmacological observations recorded in table II) maintained a normal blood-pressure, whereas in the first few weeks this dose was clearly inadequate. Reductions, to 3 g. daily at the time of writing (January, 1954), have continued; and latterly the maintenance of the desired blood-pressure has required very fine readjustments. Thus it was recently observed and verified that after a week on a daily dose of 2.5 g. the blood-pressure fell from normal to 110/70 mm. Hg, but the pressure rose to 150/90 after a daily dose of 3.5 g. daily for a further week. Such discrimination between doses differing by only 1 g. daily was not found in the initial phase of treatment with liquorice extract.

Discussion

Pelser et al. (1953a) provided the first evidence of the successful long-term treatment of Addison's disease solely with liquorice extract or its constituents. Their four patients were maintained in electrolyte equilibrium for periods ranging from one to two and a half years. The patient described here has now enjoyed good health for over a year as an outpatient and avers that this medicine is both palatable and free from undesirable effects on digestion or bowel habit.

The initial control in our patient required the large dose of 60 g. of liquorice extract daily. The absence of a favourable response earlier to half that dose tempted us to abandon this treatment. As treatment continued,

however, the initial insensitivity to this therapy was soon reversed, and the patient's present maintenance dose is 3 g. daily. Pelser and associates (1953a) also observed increasing sensitivity to liquorice therapy. They considered that there was no evidence that this resulted from regeneration of adrenocortical remnants—a view confirmed by the present observations. In the present study a cumulative action of extract of liquorice was also observed.

The action of liquorice extract is thought to be purely deoxycortone-mimetic (Borst et al. 1953, Pelser et al. 1953b). In our patient during continuous therapy with liquorice extract there were no significant changes in the results of the Kepler test or fasting blood-sugar levels to suggest any cortisone-like action by the extract. Determinations of urinary 11-oxysteroid excretion by the method of Talbot et al. (1945), slightly modified, showed that, compared with the normal range (0.15–0.40 mg. per 24 hr.) the value was below normal (0.025 mg. per 24 hr.) when no treatment was being given and above normal (0.5 mg. per 24 hr.) during treatment with 15 g. of liquid extract of liquorice daily. This suggests that the excretory products of liquorice extract may interfere greatly with the results obtained by this test. In another case of Addison's disease we sought by a modification of the method of Norymberski et al. (1953) to establish whether a similar interference disturbs the assay of urinary 17-ketogenic steroids. Apparently there is no such disturbance; for a normal value was obtained while the patient was receiving 60 g. of the liquorice preparation and 6¼ mg. of cortisone daily. It was further shown (J. M. Stowers, personal communication) that the liquorice preparation was itself a powerful reducing agent of the copper in the Talbot test for urinary corticoid assays (Talbot et al. 1945). Repeated determinations of the urinary neutral 17-ketosteroid excretion gave uniformly low results, as Hudson et al. (1953) have also found.

Liquorice therapy therefore does not appear to influence androgen metabolism. Although the skin pigmentation of our patient did not change significantly after the institution of liquorice therapy, the finger-nails appeared to become appreciably paler, suggesting that liquorice therapy may reduce melanin deposition in growing structures. This view was supported by microscopic study of the cut free ends of the nails, at various stages; but this observation has not been checked biochemically.

Patients with Addison's disease vary considerably in their sensitivity to liquorice or its constituents. Thus, Borst et al. (1953) reported that the deoxycortone-like effect of liquorice was absent in their three patients with Addison's disease, but that 10 mg. of cortisone restored fully the effect of the liquorice on mineral metabolism. I recently made a similar observation (to be published) in a patient who, on two attempts, could not be controlled adequately on liquorice therapy alone, although he responded to deoxycortone alone, and later to the combined administration of 6¼ mg. of cortisone and 60 g. of liquid extract of liquorice daily.

TABLE II—COMPARATIVE EVALUATION OF VARIOUS TREATMENTS

Treatment (in addition to ordinary diet)	Duration (weeks)	Mean blood-pressure (mm. Hg) on last day of study period	Effect
A Nil	1	85/55	—
B Ext. glycyrrh. liq. 5 g. t.d.s. 10 g. t.d.s. 15 g. t.d.s. 20 g. t.d.s.	1 1 1 1	70/55 80/55 105/80 135/80	Nil Nil Slight Definite
C Sodium chloride 12 g. daily " " " " " "	1 2 3	80/60 85/55 110/75	Nil Nil Slight
D Deoxycortone acetate (intramusc.) 5 mg. daily 2.5 mg. daily	1 1	140/80 110/70	Definite Slight
A None	1	80/60	Nil
E ₁ Ext. glycyrrh. liq. 10 g. t.d.s. Plus sodium chloride 12 g. daily	1 2	145/90 175/100	Definite Very definite
F None (following E ₁) ..	1	125/80	Cumulative
E ₂ Ext. glycyrrh. liq. 20 g. t.d.s. Plus sodium chloride 12 g. t.d.s.	½ ..	160/90 ..	Very definite ..
F None (following E ₂) ..	1½	120/80	Cumulative

As with deoxycortone, for the maintenance of the more severe cases of Addison's disease liquorice must be administered along with cortisone. A synergistic action between these two drugs has been demonstrated by Borst et al. (1953), who described a patient who remained well for at least a year while receiving 16 g. of liquorice extract and 10 mg. of cortisone daily.

Thus it seems that Addison's disease may be treated over long periods with liquorice extract or its constituents, aided when necessary with concurrent cortisone therapy. Pelsler (1954) has described a patient in whom the effect of glycyrrhetic acid on electrolyte metabolism, although satisfactory, was potentiated by small doses of cortisone. The merits of liquorice therapy are its apparent effectiveness and safety, and the absence of undesirable side-effects, as well as its palatability, convenience, and cheapness.

Summary

A case of Addison's disease, well maintained for over a year on liquorice extract alone, is described.

The optimal daily dose of liquorice extract decreased from 60 g. to 3 g. in just over eighteen months.

In addition to this increased sensitivity to liquorice extract judged by the pressor response, a cumulative action was also evident.

Liquorice extract has a useful place in the long-term treatment of Addison's disease.

I am greatly indebted to Dr. John Gray for permission to undertake these investigations, to Dr. W. Walther and Dr. C. Raeburn for their coöperation in the biochemical and histological studies, to Dr. J. M. Stowers and Dr. J. D. N. Nabarro for the determinations of urinary 11-oxysteroids and of 17-ketogenic steroids, and to Mr. F. Allen for pharmaceutical advice.

"... the study of pathology, conceived of in its widest sense, is of little value to one who is going to practise medicine unless it enables him to grasp clearly the functional changes that are produced by the anatomical changes so frequently caused by disease and seen post-mortem. For every sick person is essentially a functionally deranged organism. He may owe his symptoms to changes that are physically recognisable in his organs or to disorder in the workings of his mind or, if you prefer, of his central nervous system. A sick person is a person with morbid physiology or psychology, and the physician's business is to learn what the disorder—in its literal sense—is due to, and to apply this knowledge to remedy the defect—in other words, to 'cure' the patient. The modern trend is to use pathological knowledge to prevent disease, if that is possible, rather than to cure it. I cannot stress to you too much, therefore, the desirability of acquiring the point of view which will lead you to ask yourself in every case, 'What do the observations, of whatever nature, that I make tell me about the disease process from which my patient is suffering?' Never be intellectually satisfied with a diagnosis or a label. But it must be recognised with sadness that such an exhortation will probably affect the conduct of only the most alert students and practitioners."—Sir HOWARD FLOREY, F.R.S., in *Lectures on General Pathology*. London, 1954, p. 20.

INTRAVASCULAR HÆMOLYSIS IN CHOLERA

THE EFFECT OF OXYTETRACYCLINE

S. N. DE

M.B. Calcutta, Ph.D. Lond., D.T.M.

PROFESSOR OF PATHOLOGY

K. P. SENGUPTA

M.B. Calcutta

CURATOR, PATHOLOGICAL MUSEUM

N. N. CHANDA

M.B. Calcutta

DEMONSTRATOR OF PATHOLOGY

NILRATAN SIRCAR MEDICAL COLLEGE, CALCUTTA

THE observation of hæmoglobinuria in a case of cholera (De et al. 1952b) led us to wonder whether intravascular hæmolysis is a regular feature of this disease; and, if so, what may be its possible mechanism and effects. In an attempt to elucidate these points we have made a special study of some cases admitted to the cholera ward.

Materials and Methods

The patients came in with a history of vomiting and purging and with signs of shock. They may be divided into three groups:

Group 1.—23 patients were given the routine treatment of intravenous hypertonic alkaline saline solution followed by physiological saline solution. None had oxytetracycline (tetracycline). In each case *Vibrio cholerae* (21 Ogawa and 2 Inaba strains) was isolated from the stools.

Group 2.—7 patients received oral oxytetracycline 1000 mg. on admission with 500 mg. after two hours and then four-hourly to a total dose of 5.0 g. They were given intravenous saline solution as in group 1. Their stools contained *V. cholerae* (Ogawa).

Group 3.—7 patients in whom *V. cholerae* could not be isolated from the stools received routine intravenous saline solution as in groups 1 and 2 and served as controls. No oxytetracycline was given.

Soon after admission 5–10 ml. of venous blood was collected: of this 2 ml. was heparinised and the rest allowed to clot. The serum-bilirubin level was estimated (one-minute and thirty-minute) by the modified Malloy and Elvyn technique (Ducci and Watson 1945) and the van den Bergh reaction was determined. Hæmoglobin percentage (Sahli), erythrocyte-count, and packed-cell volume were estimated from the heparinised fraction. The supernatant plasma from the centrifuged heparinised sample was examined for the colour of hæmoglobin, which if present was measured with a photo-electric colorimeter by the acid-hæmatin method. The deposited red cells were washed thrice in physiological saline, and the osmotic fragility was determined by the technique described by Dacie and Vaughan (1938). In the cholera cases the effect of mechanical trauma on the red cells (ninety shakes per minute for half an hour in a Kahn shaker) was also noted. Samples of heparinised and clotted blood were collected similarly on the second, fourth, and eighth days, and all the above-mentioned investigations except the fragility tests were repeated.

The first sample of urine passed after the period of anuria was collected and centrifuged, and the supernatant fraction was examined chemically and spectroscopically for methæmoglobin.

Findings

The accompanying table shows the average figures worked out from the above investigations. It will be seen that in all the groups there was considerable hæmoglobin concentration on the first day: the hæmoglobin percentage was much raised (112–116% Sahli) and the

BLOOD CHANGES IN CHOLERA AND NON-CHOLERIC DIARRHŒA

Group	Day of disease	Hb % (Sahli)	Red cells (million per c.mm.)	Packed-cell volume (%)	Serum-bilirubin (mg. per 100 ml.)	Osmotic fragility (%NaCl)

	8

Mean figures have been tabulated.

erythrocyte-count (5,670,000–6,270,000 per c.mm.) and packed-cell volume (49.4–54.4%) increased. These figures gradually came down during convalescence. The one-minute or prompt serum-bilirubin level was 0 in all the cases; but the thirty-minute serum-bilirubin varied among the different groups. The average serum-bilirubin was higher (0.54–0.55 mg. per 100 ml.) on the first day in the cholera cases (groups 1 and 2) than in the controls (0.24 mg. in group 3). Besides, the patients in group 1, who received no oxytetracycline, showed on the second day a steep rise in the serum-bilirubin level (1.09 mg. per 100 ml.), which gradually fell later (see figure). In group 2, who received oxytetracycline, this acute rise of serum-bilirubin on the second day was absent, although hyperbilirubinæmia persisted even to the fourth day (0.62–0.63 mg. per 100 ml.). In the controls in group 3 the bilirubin curve remained almost flat at a low level (0.16–0.24 mg. per 100 ml.). The serum van den Bergh reaction was immediate direct negative and indirect positive.

Serum-bilirubin levels in 23 cholera patients (group 1) not treated with oxytetracycline; 7 cholera patients (group 2) treated with oxytetracycline; and 7 controls (group 3).

at which initial hæmolysis took place (see table). Only 3 cases in group 1, 0 in group 2, and 2 in group 3 showed initial hæmolysis at a saline concentration just above 0.46%, which is usually taken as normal.

3 of the patients in group 1 had hæmoglobinæmia with plasma-hæmoglobin levels of 180, 180, and 138 mg. per 100 ml., and the plasma-hæmoglobin done on the second day in a 4th patient was 96 mg. per 100 ml. The hæmoglobinæmia disappeared by the next day after it was discovered. Including the case reported earlier (De et al. 1952b) 5 cases of hæmoglobinæmia in cholera have been reported. Of these 5 cases 3 had hæmoglobinuria

also; in the 4th patient the first sample of urine voided after the period of anuria was not obtained; and the 5th patient died before passing urine. It is the first sample of urine that is likely to contain the largest amount of the abnormal pigment, which tends to disappear rapidly from the succeeding specimens. Of the 5 patients with hæmoglobinæmia 3 died later of postcholeric uræmia (between the eighth and the tenth days); 1 died in the stage of shock; and 1 had an uneventful recovery.

Discussion

All the cases of cholera, whether they were treated with oxytetracycline or not, had hyperbilirubinæmia, which was greatest on the second day. The absence of a yellowish colour in the cholera stool suggests biliary obstruction as the cause of the hyperbilirubinæmia; but a negative immediate direct van den Bergh reaction excludes this possibility. The hyperbilirubinæmia must therefore be due either to retention of a normal amount of bilirubin from anoxic or toxic injury to liver cells or to an excessive formation of bilirubin from abnormal breakdown of red cells, or to both causes.

The maximum rise of serum-bilirubin on the second day, and the persistence of hyperbilirubinæmia on the fourth day (when the patient has recovered from shock and hæmoconcentration), together with the absence of prompt bilirubin in the serum, make it unlikely that toxic or anoxic hepatic injury is a cause of the raised serum-bilirubin. The absence of any significant histological changes in the liver of patients dying of cholera also supports this contention, although such a possibility cannot completely be ruled out. On the other hand, the occurrence of frank hæmoglobinæmia and/or hæmoglobinuria in 5 cases leaves no doubt about the cause of the hyperbilirubinæmia which was subsequently observed in them, and suggests that a relatively milder and slower process of hæmolysis may explain the rise of serum-bilirubin in the others.

Cohnheim (1892) considered the possibility of red-cell damage, hæmolysis, and hæmoglobinæmia in cholera when he observed that the plasma contained potassium salts. d'Herelle et al. (1930) also emphasised the important rôle of hæmolysis in cholera, though on less secure observations, and Rogers (1922) regarded hæmolysis as the cause of coloured serum in some of his worst cases. Awny (1948) observed an increased icterus index in only a small proportion of cases of cholera, and attributed it to hæmolysis.

A low chloride content was suggested by Rogers (1922) as the cause of hæmolysis with coloured serum in cholera. Banerjee (1941) recorded very low plasma-chloride levels in cholera even after the administration of saline solution. More recently Saha and Das (1951) have reported hypochloræmia in cholera before the administration of saline solution. However, of their 22 bacteriologically proved cases 17 had plasma-chloride levels above 0.46 per 100 ml. In our study of the fragility of red cells no trace of hæmolysis was seen above this concentration in most of the cholera cases. Therefore a low plasma-chloride level can hardly be held responsible for the hæmolysis in cholera.

Awny (1948) believed that the fragility of the red cells was increased by cholera toxin or by the mechanical trauma resulting from dehydration and increased viscosity of the blood. We, however, have not detected any abnormal fragility of washed red cells either in hypotonic saline solution or after mechanical trauma. Moreover, Cooray and De (1949) have shown that the subcutaneous injection of hypertonic glucose solution sufficient to induce considerable hæmoconcentration in rabbits does not produce any significant alteration in the red cells or any hæmolysis. Further, in our controls in group 3, with equal if not greater hæmoconcentration, no hyperbilirubinæmia was found. These facts suggest that dehydration with its consequences cannot explain the hæmolysis noted in cholera.

OXYTETRACYCLINE

We have previously discussed the possibility that a hæmolysin produced by *V. cholera* destroys red cells (De et al. 1952b). The effect of oxytetracycline on the rise of serum-bilirubin level on the second day supports this hypothesis. Oxytetracycline has been found by De et al. (1952a) to exert both bacteriostatic and bactericidal action against *V. cholera* in vitro, and clinical reports (Konar and Sengupta 1951, Das et al. 1951, 1953) also suggest that the stools become vibrio-negative earlier in cases treated with oxytetracycline than in controls. These reports indicate that the antibiotic may influence the serum-bilirubin level in cholera through its adverse effect on the vibrios and thus on their production of hæmolysin. De et al. (1954) have also observed that *V. cholera* produces a thermolabile hæmolysin which acts on human red cells only in the presence of calcium salts, and that the typical hæmolytic activity is also exhibited by samples of cholera stool yielding a pure growth of *V. cholera*.

The present study was made at the height of a cholera epidemic, and random cases were selected for investigation; hence the incidence of hæmoglobinæmia recorded here may be shown to be too high when a larger number of cases are collected throughout the season. Of the 5 patients with hæmoglobinæmia 4 died, whereas only 1 of the 26 others did. It would be unwise to generalise from this limited observation, but it indicates a grave prognosis for cases with excessive hæmolysis and consequent hæmoglobinæmia. Further, the development of postcholeræ uræmia in 3 of the 4 fatal cases of hæmoglobinæmia suggests that there is a significant relation between the two conditions (see De 1953).

The effect of oxytetracycline therapy on the serum-bilirubin level in cholera is interesting. We did not start with the idea of assessing the success or otherwise of such therapy but we found incidentally that the cholera patients not exhibiting a sharp rise of serum-bilirubin on the second day had been given oxytetracycline.

The clinical reports cited above hold out very little promise of success for oxytetracycline therapy in cholera, although the vibrios in the stool disappear rather earlier. Nevertheless the present study of a small number of cases suggests this antibiotic has some definite beneficial effect on at least one, perhaps ominous, pathological process going on inside the body in cholera. Perhaps higher doses given more frequently, especially at the onset of the illness, would have more obvious clinical results.

Conclusions and Summary

30 bacteriologically proved cases of cholera, of which 23 were treated with intravenous saline solution alone and 7 with oxytetracycline also, exhibited hyperbilirubinæmia, which is ascribed to intravascular hæmolysis induced by the hæmolysin of *Vibrio cholera*. Controls without cholera but with diarrhœa and a comparable degree of hæmoconcentration did not show this change.

Oxytetracycline seems to prevent a rise of the serum-bilirubin level to a peak on the second day.

Hæmoglobinæmia with or without hæmoglobinuria was observed in 4 of these 30 cases of cholera and in 1 reported earlier (De et al. 1952b). The prognosis of such cases appears serious.

The initial hæmoglobinæmia and hæmoglobinuria may play an important part in the subsequent development of postcholeræ uræmia.

The incidence and the effects of these hæmolytic phenomena should be studied in a larger number of cholera cases.

We are indebted to Dr. A. K. Duttgupta for permission to publish, and to Dr. A. Mondal, medical officer in charge of the infectious diseases wards, for help in collecting the materials from his cases. Messrs. Chas. Pfizer supplied the oxytetracycline.

PLASMA-INSULIN ACTIVITY IN HYPOPIUITARISM

ASSAYED BY THE RAT-DIAPHRAGM METHOD

P. J. RANDLE *
 M.A., M.B. Camb.

RESEARCH-WORKER, DEPARTMENT OF BIOCHEMISTRY AND ADDENBROOKE'S HOSPITAL, CAMBRIDGE

THE insulin activity of plasma from acromegalic patients, assayed by a modification of the rat-diaphragm technique originally described by Groen et al. (1952), has been shown to be significantly greater than the insulin activity of normal human plasma (Randle 1954).

The results of similar assays of plasma-insulin activity in three authentic cases of hypofunction of the anterior lobe of the pituitary gland are presented here.

The methods, procedure, calculation, and expression of results have been described previously (Randle 1954).

The results of these experiments are presented in the accompanying table. The insulin activity of plasma from patients with hypopituitarism was significantly

* In receipt of a full-time grant from the Medical Research Council.

INSULIN ACTIVITY OF PLASMA FROM NORMAL PEOPLE AND PATIENTS WITH HYPOPIUITARISM

Case no.	Type of subject	Blood-sugar level (mg. per 100 ml.)	Glucose uptake (mg. per g. per hr.) in the presence of			Calculated plasma-insulin activity (milliunits per ml.)	Limits of error P = 0.05	N

* With this single exception, all glucose uptakes in the presence of insulin and of plasma were significantly greater than the basal glucose uptake.

N, total number of hemidiaphragms used for determining the mean glucose uptake in the presence of plasma and of insulin. The figures for normal human plasma are the mean values for seven separate determinations. The individual values have been previously published (Randle 1954).

Plasma in case A was collected 3 1/2 hr. after oral glucose 50 g.; in the other cases it was collected 2 1/2 hr. after oral glucose 50 g.

less than the insulin activity of plasma from normal people. This difference does not necessarily mean that the insulin content of plasma from patients with hypopituitarism is less than that of normal human plasma; for Ottaway (1953) observed that small amounts of growth hormone had an insulin-like effect in vitro on the utilisation of glucose by the rat diaphragm, and the level of growth hormone in plasma from patients with hypopituitarism is likely to be low. The nature of the material responsible for the insulin-like activity of human plasma in the rat-diaphragm assay has yet to be satisfactorily determined, but these results and the results of similar studies in acromegaly (Randle 1954) suggest that the level of this material in the plasma is influenced by the activity of the pituitary gland.

The possible use of this technique in the diagnosis of hypopituitarism and in assessing the activity of the disease process in acromegaly is being investigated further.

Park (1952) and Bornstein (1953) have attributed the insulin-like effect of normal rat plasma in the rat-diaphragm assay for insulin to non-specific effects of plasma-protein. The results presented here show clearly that this hypothesis cannot explain the insulin activity of human plasma in the rat-diaphragm assay, since plasma samples from two authentic cases of hypopituitarism showed diminished insulin activity in the rat-diaphragm assay despite their normal protein content.

I wish to thank Prof. F. G. Young for much helpful advice and criticism during these investigations; Dr. L. C. Martin, of Addenbrooke's Hospital, for permission to study cases A and C; Prof. M. L. Rosenheim and Dr. J. D. N. Nabarro, of the medical unit, University College Hospital, London, for permission to study case B and for assistance in the study of this patient; Dr. N. R. Lawrie, of the John Bonnett Clinical Laboratories, Addenbrooke's Hospital, for plasma-protein determinations in cases B and C; and Miss D. Cope for technical assistance in the assays. The cost of this work was largely defrayed by an expenses grant from the Medical Research Council. Messrs. Boots Pure Drug Co., Ltd., supplied the crystalline insulin.

A SENSITIVE DIGITAL PLETHYSMOGRAPH

D. G. MELROSE R. B. LYNN

B.M. Oxfd M.D. Kingston, Ontario, F.R.C.S.

ASSISTANT LECTURERS

R. L. G. RAINBOW A. G. WHERBELL

SENIOR TECHNICIANS

DEPARTMENT OF SURGERY, POSTGRADUATE MEDICAL SCHOOL, LONDON

ALTHOUGH the most frequent presenting complaint of a patient with peripheral obliterative vascular disease is intermittent claudication, the deficiency in the blood-supply to the muscles rarely leads to loss of the affected limb. It is impairment of the blood-flow to the skin of the extremity that produces at first nutritional changes, then gangrene of the digits, and finally loss of the digits or the limb by amputation.

Thus it is of the greatest practical importance to be able to assess the blood-flow in that part of the limb in which obliterative arterial disease has the most serious consequences—i.e., the digits. The greatest limiting factor to date has been the lack of sensitivity of the available plethysmographs. This limitation has been overcome largely by taking advantage of the high

sensitivity of the R.C.A. transducer tube (no. 5734). The possibilities of using this sensitive valve have been explored previously (Burton 1953, Clamann 1951), but more recently workers have felt that the electric circuits required such a high degree of stabilisation as to make them clinically unpractical (Simeone et al. 1952). Studies in this laboratory have led to the incorporation of the valve into a stable electric circuit, and the mechanical alterations produced by the pulse wave are converted into electrical changes, suitably amplified and photographed. This plethysmograph has proved stable, sensitive, and practical for the clinical study of the character and responses of the digital pulse waves in the fingers and the toes of normal people and of patients with disorders of the peripheral arteries.

Apparatus

The device is an R.C.A. 5734 transducer valve coupled to a light aluminium diaphragm 2 in. in diameter and 0.008 in. thick. The valve forms part of a valve-voltmeter circuit driven by suitably stabilised high-tension (H.T.)

Fig. 1—Details of pick-up assembly.

and low-tension supplies. Details of the construction of the pick-up are shown in fig. 1. Although they are simple, considerable care must be exercised in construction to secure very close tolerances between the valve and the brass sleeve, and between this sleeve and the outer case. In particular, care must be taken to avoid rotation of the valve, and the method of construction prevents this without distortion of the valve.

The valve spigot must be clamped to the diaphragm with the amplifier adjusted to maximal sensitivity and set to zero, thereby avoiding mechanical distortion. The locking nuts are sealed to the diaphragm spindle with shellac.

Since the transducer valve is essentially a miniature triode whose plate is mechanically adjustable with reference to the cathode and grid, it may be considered as a variable resistance forming with its anode load a potential divider network across the H.T. supply. With small angular movements of the anode control spigot the change in output voltage or divider network potential is substantially linear. This movement is necessarily small and does not exceed $\pm 0.5^\circ$. Under influence of this movement and with an anode load of some 75,000 ohms the output expected is ± 20 V. It will be noticed that the output is phase-sensitive. A normal valve voltmeter of cathode-follower type is used, half the circuit being directly coupled to the transducer anode, and the

deflection may be set to a convenient magnitude, and the incorporation of a series of switched fixed values of resistance produces a variable sensitivity control. With the diaphragm in use and a 100,000 ohms anode load with a H.T. line of 255 V a volume displacement of 0.1 c.cm. produced a voltage change of 1.75 V at the transducer anode.

To obtain stability of the valve-voltmeter circuit the H.T. supply is gas-tube stabilised and the heater fed from a constant-voltage transformer, because the transducer valve is particularly susceptible to variation in the heater. To facilitate adjustment of zero control a centre zero meter of 500 μA full-scale deflection is connected in series with the galvanometer.

The apparatus is completely stable at low sensitivity—i.e., in the range of 0.25-0.001 c.cm.—but thereafter some instability develops. Random changes of temperature of the air column

other half being coupled to a balance potential obtained from the H.T. line via a variable potentiometer forming a zero control (fig. 2).

Any change of anode voltage at the transducer due to spigot deflection will cause a shift in the current distribution of the valve-voltmeter arrangement, and an out-of-balance voltage will appear at the cathodes. If the galvanometer of the recording camera is then connected between these cathodes with a suitable resistance in series, the light beam will be deflected proportionally to the out-of-balance voltage produced by the change of voltage in the transducer anode. By the use of a variable series resistance the galvanometer

in the transducer head and connecting tubes, together with thermal drift of the valve, are partly responsible. Local alterations in the pressure of the environment are even more important, but with care these can be minimised. Calibration has been done with a Burroughs

Wellcome microsyringe. Comparison with the Goetz (1949) plethysmograph indicates that the accuracy of this calibration is virtually unaffected by any build-up of pressure within the closed system. The over-all response is substantially linear over a range of volume displacement between 0.25 and 0.0004 c.cm. and from zero frequency to 15 cycles per second (fig. 3).

Fig. 4—Pulse volumes from finger-tip in healthy people at sensitivities 2 and 3.

Fig. 3—Graph of response to volume displacement between 0.02 and 0.002 c.cm. and from zero frequency to 15 cycles per second.

Clinical Observations

The digit being studied is enclosed in a metal collecting cup sealed to the finger or the toe with 'Sealastik,'* which does not cake or constrict, and therefore does not interfere with the blood-flow. Thick-walled fine-bore rubber pressure-tubing leads to the transducer mount. When blood-flows are being calculated, a venous-occlusion collecting cuff is placed at the base of the digit being studied, or, in special circumstances, when the flow is exceedingly rapid, at the wrist or the ankle with due recognition of the error so incurred (Cranley et al. 1952, Goetz 1946, Wilkins et al. 1938). The pulse-volume deflections are expressed in c.mm. per 10 c.cm. of digit, and the blood-flows in ml. per 100 c.cm. of digit a minute. Air conduction has proved quite satisfactory, and the sensitivity is such that it fails to detect a recordable pulse volume or blood-flow only in the

* Manufactured by Expandite Ltd., Cunard Road, London.

Fig. 5—Resting pulse volume in toe in patient with Buerger's disease : a, at rest before operation ; b, twenty-four hours after lumbar sympathectomy ; c, on second postoperative day ; d, on sixth postoperative day.

Fig. 6—Blood-flow shown by venous occlusion : a, before cervicodorsal sympathectomy in Raynaud's disease ; b, on fifth postoperative day.

presence of advanced arterial obliteration or severe arterial spasm, when a functioning circulation in the digit is, for all practical purposes, non-existent.

The pulse volume from the finger-tip of a healthy person is illustrated at two sensitivities in fig. 4, and from the toe of a patient with Buerger's disease before and after lumbar sympathectomy in fig. 5. Blood-flows obtained by the venous-occlusion method are

Fig. 7—Digital blood-flow and pulse volume before and after ulnar-nerve block.

illustrated before and after five days after cervicodorsal sympathectomy for Raynaud's disease in fig. 6. The digital blood-flows and pulse volumes are plotted against each other in fig. 7 before and

after ulnar-nerve block in a patient with advanced sclerodactyly. The close relationship between the two is apparent—a fact that has been confirmed by Burton (1939). The plethysmograph described here has been under study in this laboratory for more than a year, and during this time it has satisfied the requirements of stability, sensitivity, and accuracy. The same transducer valve has been in constant use in this period, which is proof of its ruggedness unless grossly mishandled. Finally, the valve is inexpensive and easily assembled, and replacements are readily obtained.

METASTATIC CARCINOMA OF THE THYROID SUCCESSFULLY TREATED WITH THYROXINE

H. W. BALME
 M.A., M.D. Camb., M.R.C.P.

FIRST ASSISTANT, MEDICAL PROFESSORIAL UNIT,
 ST. BARTHOLOMEW'S HOSPITAL, LONDON

The treatment of simple goitre with thyroid has been reviewed by Greer and Astwood (1953). Shrinkage takes place, probably because the administered hormone leads to a corresponding suppression in the output of the gland. No toxic effects are observed unless doses in excess of physiological requirements are given (Riggs et al. 1945, Greer 1951, Danowski et al. 1952, Perlmutter et al. 1952).

Carcinoma of the thyroid gland is not likely to respond in the same way as simple goitre unless it is well differentiated and still depends to some extent on pituitary thyrotrophic hormone. In the case described here a highly differentiated tumour, with widespread pulmonary metastases, was shown to depend on thyrotrophic hormone and responded favourably to prolonged medication with sodium-l-thyroxine.

Case-report

A woman, now aged 40, was first seen twenty-one years ago with a painless lump in the right side of the neck, thought to be a tuberculous gland. This was treated by radiotherapy without effect. Fifteen years ago a second and smaller lump was noticed, nearer to the midline on the same side. Eleven years ago slowly increasing dyspnoea on exertion was first noticed, and eight years ago mass radiography revealed widespread mottling throughout both lung fields. This mottling has very slowly progressed during the succeeding years. Four years ago the patient was admitted to Woolwich Memorial Hospital, where the first lump was excised; on section this was found to consist of apparently normal thyroid tissue. The second lump was then excised and showed the same histology. Since it seemed probable that these represented local metastases of carcinoma of the thyroid, total thyroidectomy was done, but no neoplastic focus could be identified in the excised gland. The patient was then referred to St. Bartholomew's Hospital for radiotherapy, under the care of Mr. I. G. Williams, and a course of 5500r was given to the neck at 250 kV in thirty days. Three years ago a third nodule was noticed in the neck and was removed; on section it was found to be composed of colloid-containing thyroid acini showing evidence of hyperplasia. Though it was impossible to diagnose thyroid carcinoma in the specimen, the cellular irregularity was greater than is usually seen in simple hyperplasia.

Radiography of the chest showed widespread mottling of innumerable small metastases throughout both lungs, but no other metastases were found elsewhere, and radiographs of the skeleton were normal.

Investigations.—A tracer dose of radioactive iodine was given; of this 43% was excreted in the urine in forty-eight hours, but the greatest uptake in the neck reached only 10%; no direct counting over the chest was attempted at this time. A second tracer dose was given five months later. The greatest accumulation of radioactivity was found in the chest, reaching 30% of the dose at twenty-four hours; the uptake in the neck reached 9% only, and it is likely that much of this was due to scatter from the chest. The test was repeated two days later with carrier iodide to simulate a therapy dose; 30% uptake in the chest and 9% in the neck were again recorded.

Respiratory-function tests were kindly made by Dr. D. V. Bates. The patient was shown to have a normal mixing efficiency as regards gases in the lungs and a normal uptake of carbon monoxide, but a greatly reduced vital capacity (2190 c.cm.) and maximal breathing capacity (47 litres a minute and 42 litres a minute on two consecutive runs). These findings strongly suggested that the dyspnoea was due to interference with distensibility of the lungs and not to emphysema or to bronchospasm.

Electrocardiography.—An electrocardiogram was normal.

Screening of the chest showed no evidence of enlargement of the right ventricle, but it was felt at this time that a real danger of progressive cor pulmonale was present, although dyspnoea was not yet severe and the patient's general health was still good.

Treatment with radioactive iodine seemed indicated, and on Sept. 11, 1951, a dose of 20 mC was given by mouth. Of this 56% was excreted in forty-eight hours, the uptake in the chest reaching 35% in twenty-four hours. Two months later a fourth tracer dose showed a maximal uptake in the chest of 46% at twenty-four hours, and a second treatment dose was then given, this time of 102 mC. A fairly prolonged radiation sickness followed this, and the patient did not recover normal vitality for about two months. Transient lymphopenia developed but no dangerous depression of the marrow.

A further tracer study on June 19, 1952, nine months after this last treatment, showed that the uptake by the lungs had now risen still further, reaching 56% of the dose at twenty-four hours, with no demonstrable uptake in the neck. Calculation (Oddie 1951) showed that the therapeutic doses should have provided local irradiation of about 10,000 r.e.p. throughout the lungs. It seemed that effective ablative doses of radioactive iodine would have to be prohibitively high, and X-ray therapy also, if an adequate response were to be obtained.

Treatment with thyroxine was therefore started in the hope that the metastases might behave like nodular goitre and slowly regress. L-thyroxine was used because it contains less non-hormonal iodine than does the racemic form, and less than thyroid extract, and would not therefore interfere with any subsequent tracer studies. Sodium-L-thyroxine was started on July 16, 1952, in a dosage of 0.1 mg. daily, which was slowly increased until by Oct. 7 the patient was receiving 1.0 mg. daily, with the production of signs of mild toxicity. The dosage was reduced to 0.7 mg. daily, at which level no symptoms were produced, and the patient was then readmitted for further tracer studies. On Dec. 15, 1952, 99% of an intravenous tracer dose was excreted in forty-eight hours, without any demonstrable uptake either in the chest or in the neck. Thyroxine was then discontinued, and four weeks later, on Jan. 12, 1953, the patient was readmitted for further study. She now presented the typical appearance of hypothyroidism; the uptake of radio-iodine in the chest reached 26% of the dose at twenty-four hours, with no demonstrable concentration elsewhere.

Further Progress.—Since then she has been maintained on thyroxine, without intermission, in a dosage of 0.5 mg. daily. There has been a slow but considerable reduction in dyspnoea; the lung-function tests have been repeated and show a rise in the maximal breathing capacity, from 47 litres a minute to 79 litres a minute, although the vital capacity has remained unaltered at 2070 c.cm.; and there is now a slight but definite clearing of the X-ray shadows in the lungs.

Discussion

I am indebted to Dr. G. J. Cunningham for his report on the histology of the local recurrence in the neck. The tumour here was well differentiated, and it is likely that the pulmonary metastases are similar to it. This is confirmed by the ability of the pulmonary metastases to pick up iodide, as the tracer studies showed; and the patient's euthyroid state despite total thyroidectomy was presumably attributable to their activity.

The suppression of iodide uptake after treatment with thyroxine parallels that observed in healthy people both in its degree and in its duration (Greer 1951, Morgans et al. 1952). It was followed by a phase of rebound hypothyroidism, as in healthy people (Farquharson and Squires 1941). It is reasonable to suppose that the mechanism of this lies in the suppression, by the administered hormone, of the pituitary output of thyrotrophic hormone, as in healthy people, and the resultant diminution in activity of the thyroid gland. This would indicate the dependence of the pulmonary thyroid tissue on normal thyrotrophic stimulation from the pituitary.

Regression of the metastases after treatment with thyroxine was shown by clinical improvement, with lessening of dyspnoea subjectively and a better per-

formance of objective tests of lung function; and it has been confirmed by definite clearing of the X-ray shadows in the lungs. (I am indebted to Dr. G. Simon for the interpretation of these films.)

Summary

A case of well-differentiated thyroid carcinoma is described in which very numerous functioning deposits in the lungs proved resistant to treatment with radioactive iodine, but now appear to have been satisfactorily suppressed as a result of prolonged treatment with thyroxine.

This patient was in the first place under the care of Mr. I. G. Williams, and my thanks are due to him and to Dr. A. E. Jones for permission to publish her case. As an inpatient she was under the care of Prof. R. V. Christie, to whom I am grateful for permission to publish and for help with the preparation of this paper. The radio-iodine studies were undertaken by the Department of Physics, and I am indebted to Prof. J. Rotblat and to Mr. G. M. Owen for the great deal of careful work they have done.

Preliminary Communication

TOXOPLASMOSIS IN CHILDHOOD

PATIENTS with unexplained pyrexia of 7–10 days' duration accompanied by generalised lymphadenopathy and sometimes by a rash and splenomegaly are commonly seen in the outpatient department of a children's hospital. A blood-count shows a leucocytosis of 10,000–15,000 per c.mm. with an increase in the proportion of polymorph cells, a threefold or fourfold increase in the absolute eosinophil-count, and no "glandular fever" cells. The Paul-Bunnell test is negative despite a reasonable clinical diagnosis of infectious mononucleosis.

Throughout the world it has been found that up to 50% of apparently normal adults have a positive dye test for toxoplasmosis, while less than 10% have complement-fixing antibodies. In toxoplasmosis the complement-fixation test is believed to become positive later, and its titre to fall more quickly, than does the dye test. Although domestic animals are presumed to be the reservoir of infection, apart from congenital toxoplasmosis little is known of how or when man becomes infected with toxoplasmas or whether the initial exposure to the parasite, leading to the production of antibodies, is invariably unassociated with symptoms.

The lack of explanation for the numbers of cases of children with pyrexia and lymphadenopathy, and their resemblance to known cases of acquired toxoplasmosis,

RESULTS OF DYE TEST AND COMPLEMENT-FIXATION TEST IN 20 CASES OF CHILDREN WITH UNEXPLAINED PYREXIA AND LYMPHADENOPATHY

Case no.	Dye test (titre)	Complement-fixation test (titre)
1	1/512	1/32
2	1/32	1/32
3	1/64	1/16
4	1/256	1/16
5	1/64	1/64
6	1/64	1/16
7	1/256	Anticomplementary
8-20	Negative	Negative

led me to wonder whether this condition might represent the first, antibody-stimulating exposure to toxoplasmas, resembling a primary tuberculous complex.

INVESTIGATION

Sera from 20 children and young adults suspected on clinical grounds of having glandular fever were all found to give a negative Paul-Bunnell test. Toxoplasma dye and complement-fixation tests were made, and the findings are shown in the accompanying table.

COMMENT

These results were unexpected, because of both the number of positive findings and of the high titres. It is still difficult to know, in the absence of recognised signs of toxoplasmosis, what attention to pay to positive serological findings, but a titre of 1/8 for the complement-fixation test is generally regarded as of some diagnostic significance. Of the 20 cases 6 had titres in excess of this; while in a 7th case where the serum was anti-complementary the dye-test titre was 1/256—four times as high as that usually found in the symptomless adult.

These preliminary findings are far too incomplete for any firm conclusions. A much larger series of cases of glandular enlargement must be investigated, and a long follow-up is being undertaken to observe changes in antibody titre. Also the hæmatological findings must be accurately correlated with the serological. But the present data do lend support to the belief that some, at least, of the cases of apparently non-specific generalised lymphadenopathy with pyrexia in children may be due to toxoplasma infection, and that the positive serological tests so often found in the symptomless adult may be a residuum of such infection.

Reviews of Books

Rh-Hr Blood Types

Applications in Clinical and Legal Medicine and Anthropology. ALEXANDER S. WIENER, M.D., F.A.C.P., senior serologist to the office of the chief medical examiner of New York City. New York: Grune & Stratton. 1954. Pp. 763. \$11.50.

An Rh-Hr Syllabus

The Types and their Applications. ALEXANDER S. WIENER. New York: Grune & Stratton. 1954. Pp. 82. \$3.75.

BETWEEN 1929 and 1953 Dr. Wiener and his co-workers published 333 papers on the Rh-Hr blood types. The first of the two volumes reviewed here gives a full list arranged in years. The papers have appeared not only in the United States but also in British, French, and Italian journals and some others. From these numerous and often important writings Dr. Wiener has selected 84 to represent his contribution to every aspect of the subject. As they have been reproduced from the originals by a photographic process, the book inevitably contains a mixture of sizes and shapes of type which makes for difficult reading; sometimes the reproduction is not too clear and some of the more complex tables need a magnifying-glass. It may be useful to have this collection under one cover, but the relatively few experts directly interested in the subject are likely to have read the principal papers already and probably possess reprints. The non-expert will hardly tackle so difficult a set of papers, and in his *Rh-Hr Syllabus* Dr. Wiener himself has in fact provided them with a much shorter and simpler account of his work.

The *Syllabus* is an excellent little monograph, containing all that anyone not actually pursuing research into blood-groups needs to know about the Rh-Hr blood-group system and the pathological conditions in which it is concerned. It begins with a series of definitions of fundamentals, and the next two chapters, on Rh antibodies and on the serology and genetics of

the Rh-Hr types, contain short didactic discussions, illustrated by clear diagrams. A fairly long and remarkably informative chapter on erythroblastosis foetalis is followed by short chapters on blood-transfusion, anthropology, and medicolegal applications. Unfortunately Dr. Wiener's views on nomenclature introduce difficulties for many of the readers who would benefit most from his book. In this country the CDE nomenclature is in everyday use; but, as is well known, Dr. Wiener regards it as misguided and misleading, and will have none of it. As things stand, the ordinary student needs the help of books that, unlike Dr. Wiener's, make a fair job of collating the two systems. But it is a measure of his skill that he makes his subject plain despite the complexity of the notation which the devotees of the theory of multiple alleles find necessary for the expression of their ideas.

Spot Diagnosis

Volume 1. Compiled by the Editors of *Medicine Illustrated*. London: Harvey & Blythe. 1954. Pp. 128. 7s. 6d.

THIS is an entertaining and teasing book. The reader is invited to examine a photograph and consider some clues; he must then make a diagnosis, and answer some questions, before turning to the right answer on the next page (rather too handy for those who readily succumb to temptation). Most of the pictures have appeared under similar examination conditions in *Medicine Illustrated*. The game is both instructive and aggravating; for the baffled diagnostician learns from his mistakes, yet complains that he would have done better, of course, in the flesh or with a coloured photograph. And he may be annoyed when a non-fluctuant swelling turns out to be a cold abscess, even though the answer generously excuses him from blame in this case. One or two of the conditions are on the rare side, but then many of the commoner diseases do not lend themselves to this form of demonstration. The answers include brief notes on diagnosis and treatment, and at the end of the book there are summaries of some recent developments in medical treatment. This volume is the first of a series.

Medical Electronics

G. E. DONOVAN, M.D., M.Sc., D.P.H. London: Butterworth. 1953. Pp. 215. 30s.

THE aim of this book is "primarily to provide a bird's eye view of the uses of electronics in medicine." The list of contents is impressive, including such subjects as X rays, radioactive isotopes, television, electron microscopy, amplifiers, phono-electrocardiography, electromyography, servo mechanisms, and cybernetics. But in his effort to cover so much ground so quickly the author does not always carry the reader along with him.

Much electronic terminology is used without additional or simplifying explanation: "the p-n-p junction triode," "frequency selector and clipper, pulse shaper and delay circuit," and "the usual arrangement of push-pull stages with cathode degeneration of in-phase voltages" are phrases unlikely to convey any clear idea to those not engaged in electronic work. The almost complete absence of cross-references is tiresome: thus a porous-plug transducer is mentioned on p. 88 but not in the chapter on transducers, while gas amplification is not explained in the chapter on photo-electric cells, though the reader is told earlier that gas amplification does not take place in ionisation chambers.

The illustrations are of mixed quality: some, such as those in the chapter on electron microscopy, are good, especially the comparison between the electron microscope and the optical microscope; others, showing merely the outside appearance of cabinets, are unhelpful. Dr. Donovan believes that detailed circuit diagrams are not necessary for an understanding of the principles involved in an apparatus, and that may be so; but there is still a real need for the imaginative use of block schematic diagrams.

The preface suggests that doctors who are not already familiar with the applications of electronics to medicine may find the book of interest; but those who are not well versed in electronic terminology will find much of it perplexing—though they may profit from the accounts of the various applications. Physicists, research-workers, and electronic engineers will find some useful references.

Consider the use of

'Largactil'
trade mark brand
CHLORPROMAZINE HYDROCHLORIDE

in these indications

1 An adjuvant in various anaesthetic techniques before, during and after operation

2 Symptomatic treatment of various acute phases of mental disease, and also of the minor psychological disturbances met with in general practice

3 For the treatment of intractable nausea and vomiting due to a variety of causes

These are the uses of 'Largactil' with which clinical studies have been mainly concerned. The extent of the clinical usefulness of 'Largactil' in other fields, including its use to enhance the effect of analgesics in the control of severe pain, is still under investigation.

Detailed literature available on request.

PRESENTATIONS

10 and 25 mgm. sugar-coated tablets. 2 c.c. ampoules of 2.5 % solution for injection. 5 c.c. ampoules of 0.5% solution for injection.

The Bombs

THE terrific explosion of the hydrogen bomb last month was one of those dramatic events that display a dangerous situation and compel us to consider where we are going. Absorbed though we may be in our own affairs, we have to adjust our minds to the probability that if there is another world war this weapon will be used on our behalf. For many millions this probability means that they must examine afresh their opinions on the ethics of war.

In such an examination we may begin by noting that within almost all human groups the members are forbidden to kill each other. Man is a social animal whose success has generally depended on the support of his fellows, and, whether the group is small or large, homicide within it is regarded as a crime—often, as in our own country, as almost the gravest of crimes. On the other hand, there is no social objection to the destruction of an enemy *outside* the group: on the contrary, when two groups are at war, the very code of loyalty which prevents internal killing enjoins external killing, and the aggressive violence which is criminal at home becomes meritorious abroad. Moreover, so strongly social are mankind—so devoted to their own group—that to the large majority this apparent anomaly of conduct comes quite naturally; and they will go to equal lengths to kill their foes or to save their friends. Distinguishing thus sharply between “our side” and the others, they readily extend protection to anyone who wants to join their group—even yesterday’s enemy. Indeed civilisation has been made possible only by the formation, in this way, of larger and larger groups whose members feel that in essentials they are all on the same side, and who therefore accept a code which stops them from killing each other.

In the past, fifty years this process of social coalescence has gone on much faster—so much so that in the present Cold War most of the nations belong to one or other of two opposing groups, not unevenly matched in numbers. The more hopeful among us take comfort in the thought that the creation of these two immense groups, each securing peace within its borders, may be the last stage on the way to the creation of a single world community—a community of which every human being is a member, and whose protection he enjoys. Through the centuries this goal of human unity has been set before us alike by the idealist and by the realist—the one asserting the brotherhood of man, the other demonstrating the artificiality and impermanence of the political and racial boundaries which appear so formidable. (Both in this idealism and in this realism no small part has been played by our own profession, whose members, in undertaking to do their best for any man, woman, or child at any time, have reflected, however imperfectly, the best of Christian teaching and Greek thought). Given time, there can in fact be little doubt

that these ideas will be accepted: the remaining groups will in one way or another be fused, and thenceforward only those who are outcast from the world community will feel justified in taking the lives of others of their own species. But we do not know when or how this will happen: and meanwhile the division of the world into two major groups means that though we have far more potential friends we also have far more potential enemies. Nor has our progress towards a World State in the future lessened the antagonism, or civilised the methods, with which war is waged in the present. On the contrary, our struggles have become more intense; having begun to fight, we find it harder to break off the engagement and reach an honourable settlement; and our techniques of killing, though in some ways less horrible than our ancestors’ personal use of fire and sword, have a recklessness which suggests a blunting of moral values. Certainly the conventions of war have changed astonishingly within a few decades.

To the primitive member of a group, the declared enemy is always something to be destroyed, and the more thoroughly the better. We have lately witnessed dreadful examples of such barbaric warfare. But human societies have never consisted entirely of mental myopes, and even before the time of the greatest religious teachers many nations adopted conventions designed to prevent the worst atrocities of war. In Europe Christian influence increased the power of such conventions so greatly that a time came when the right to kill and the methods of doing so were strictly circumscribed by rules; and any combatant breaking these rules exposed himself to the contempt of neutrals. Those who are old enough to remember the earlier part of the first world war may recall the shocks of horror that went through this country at the report that our enemies were using dum-dum bullets, at their shooting a woman for helping prisoners to escape, at their use of poison gas, and above all at their attacks on liners conveying civilians and on hospital ships conveying the wounded. Of all the motives that inspired our nation in 1914–18 none perhaps was stronger than the determination to defeat a country which in these ways flouted the rules of war, and which openly declared that the end justified the means; and it was in the hope of preventing the triumph of such doctrine that great numbers of young men of the Allied Forces gave their lives. In 1939 the cause presented to their successors was not perhaps very different; but this time there was no surprise at our enemy’s bombing of open towns, and the minds of nearly everybody were soon adjusted to the policy of retaliation which ended in the destruction of so many Continental cities and so many of the people in them. By the time the first atom bombs were dropped on Nagasaki and Hiroshima we had come a long way from the dum-dum bullet. Rightly or wrongly, we had reconciled ourselves to the annihilation of any member of an opposing group, whether old or young, man or woman, under arms or not. And to annihilation the atom bomb added the possibility that our action would so damage the genes of survivors that our enmity would reach even their descendants.

On the practical rather than the moral plane, the use of new weapons requires further thought because they are becoming so powerful that their effects may

soon be incalculable. Many will be grateful, therefore, to a member of our profession, Prof. ALEXANDER HADDOW, both for his plain statement of the risks now developing and for his proposals for meeting them.¹ The events in the Pacific, he says, bring to an end the notion that the area of danger can have any but relative meaning, and he goes on to speak of the subtler menaces arising from the liberation of radioactive products. "We approach," he thinks, "the time when future risks must be envisaged on a terrestrial scale, with more than a hint of new kinds of catastrophe from increased physical incalculability"; and this opinion has since been given further point by the announcement² that there is now no obstacle to making "the most dreaded weapon of all"—a cobalt bomb which on explosion is transformed into a radioactive cloud that will travel thousands of miles, destroying all life in its path.

"The solution," Professor HADDOW continues, "is one for statecraft and not for science as such. Yet the issue is so universal, and the Governments of the world are so compromised in their attitudes towards it, that we must despair whether there exists in fact either the mechanism or the will. . . . If all solution is beyond the present means, the question must be raised whether the representatives of world science itself, imbued by some sense of humane responsibility, can assist in the judgment."

"While the crisis is unlikely to be affected by the endeavour of any single individual today, such would not necessarily be so were the issue transferred, under the aegis of the United Nations, to a *concilium* of world science, representing especially physics, chemistry, biology, and medicine, representative also of their nationalities, yet supranational in outlook, of an authority transcending that of the politician, and with an unimpeachable primary loyalty to humanity as a whole. From such a body, and possibly from such a body alone, might we expect a factual appraisal and an advocacy of policy of such overwhelming weight as to commend itself to the whole of the civilized world."

"International relations is clearly not a discipline susceptible to the scientific method, yet it could perhaps be affected by the outlook of science, and some approximation made towards an analysis of the contemporary situation, more objective than those monumental travesties to which, from one side or the other, we are sufficiently accustomed."

Three months ago we suggested that in facing this further year of peril the chief need was to keep a sense of proportion. That need remains; but a sense of proportion is not maintained by pretending that very big things are really quite small. In the discussions of the past few weeks some have argued that an unnecessary fuss is being made about a weapon which is only the latest in a long series of lethal developments in the art of warfare—from the bow and arrow to the bacterial toxin. To this the answer is that in this process of development there are certain profoundly significant points, of which one was the agreement to the mass bombing of cities, another was the first use of atomic fission for the same purpose, and a third is the possibility that we are moving from the indiscriminate to the incalculable. At any such point a pause for thought is proper; and before we teach ourselves to regard the hydrogen bomb as a legitimate means of protecting our civilisation we should consider what effect such protection is having on the civilisation itself. Man often kills the things he loves; and if by civilisation we mean freedom of speech and belief, a good conscience towards others,

and a respect for human life and personality, we may find that it is being sacrificed in its own defence. There are indeed already signs of our acquiring a barbarity of thought that makes us unfit to be its defenders.

The moralists say that if an end can be reached only by evil means, that end must itself be evil; and few of us can have any real doubts about the wrongness of wiping out a city or a nation with a bomb. On the other hand the mere existence of this invention is not necessarily an evil, and it may even prove our salvation if it induces the leaders on both sides to consider objectively whether the differences between us really justify and necessitate the continuance of an undeclared war carrying such risks for everybody. At present both sides are strong in armaments but nevertheless afraid; and the reason for their fear is largely that neither ceases for a moment its efforts to undermine the position of the other. Is it too much to ask that, as a first step towards the return of human relations, both should call a truce to this aggressive propaganda? Profoundly though we may disapprove of the Eastern régimes, we should remember that their citizens think they have reasons for no less disapproval of the West; and in trying to preserve a sense of proportion we should not forget that half the nations of the Free World were once our own enemies, either because we hated their tyrannies or because they hated ours. If by curbing our fears and restraining our threats we can avert a conflict which will ruin both worlds, the two different civilisations may be able to live side by side and eventually absorb what is best in each other. On a historical view such coalescence of rival groups is very far from being impossible; and its attainment must be the aim of all who recognise that, for survival, all men must come to regard themselves as members of a single group—in which homicide, by any method, is forbidden.

Detection of Tuberculous Contacts

BURIED beneath the mortality-rate and the notification-rate lies the epidemic pattern of tuberculosis, as secret and tenuous as the mycelium of a mushroom-bed. Neither rate gives a reliable map of its ramifications: the deaths have fallen fast in the last five years, the notifications hardly at all, as Dr. TATTERSALL¹ has pointed out in our correspondence columns; indeed in Scotland in 1953 they were slightly higher than in 1952. Nevertheless, the greater the proportion of cases detected, the more informative the notification-rate will become. The situation is complicated by the fact that patients with advanced disease are now living longer and perhaps adding to the risk to other people. Our greater success in making the tuberculous sputum-negative may not offset this as much as we hope if, as Dr. STEWART and Dr. VAN ZWANENBERG suggest in their letter this week, we cannot rely on bacteriology in determining the infectiousness of a particular patient. As things stand, it is still very hard to assess either prevalence or risks. But our lack of a perfect map need not prevent our doing much more than we are doing to contain this disease.

A memorandum from the Ministry of Health,² designed to help medical officers of health to review

1. *Times*, March 30, 1954, p. 7.
2. *Ibid.*, April 8, 1954, p. 5.

1. Tattersall, W. H. *Lancet*, April 3, 1954, p. 730.
2. Prevention of Tuberculosis. Circular H.M.(54)30.

their own programmes of control, rightly insists that the chief cause of primary infection is close contact of a susceptible subject with an infected person. Spread from other causes—from inhalation of infected dust, for instance—is nothing like so important. The first job of the preventive team, then, is to find every infected person and notify him. Notification of every case discovered, indeed, is an essential contribution to prevention which all clinicians, in or out of hospital, ought to make. For only when a case has been notified can the M.O.H. set about finding out where the patient got his infection and whether he has infected others. The Ministry thinks that if as much effort were put into tracing sources and contacts of tuberculosis as is put into tracing sources of typhoid or contacts of smallpox, we should make faster progress. Contacts should not only be examined: they should be kept under observation for a time to see whether they are incubating the disease, or whether, in common with the index case, they are exposed to a source of infection not yet detected. Children, adolescents, and young adults naturally need the closest supervision; and all tuberculin-negative contacts, of whatever age, should be given whatever protection B.C.G. vaccination confers. Local health authorities are now at liberty to give this vaccine to children about to leave school, and the Ministry has published a circular³ and memorandum⁴ on the subject.

In tracing sources of infection, skin tests can be very useful, and they could be applied much more widely than at present to investigate the family contacts of an infected child, and so to trace the person by whom he was infected, or even the source of infected milk. Surveys of the family contacts of tuberculin-positive school entrants have yielded a high proportion of infected adults; and the Ministry thinks that further studies of this kind would be valuable. Skin testing at other ages may also be informative: thus when a child seen at a chest clinic is found to have a primary infection or adult-type tuberculosis, the skin testing of his class and teachers at school may reveal an unknown case in another child or an adult. Indeed, skin tests could be used, STEWART and VAN ZWANENBERG believe, to map the incidence of infection in various age-groups, and in different schools, throughout the country. This would give us a picture of the black spots, and, as the years go by, a measure by which to judge the success or failure of our attempts to control the disease. In areas where not all milk is pasteurised the discovery of a high proportion of tuberculin-positive children may reinforce a campaign to get rid of bovine infection. Repeated radiographic examination of school staff seems a reasonable precaution, and one to which no teacher ought to object—though it is not always easy to be enthusiastic about an investigation when one's livelihood depends on the result. The Ministry favours the selective use of mass radiography rather than the examination and re-examination of large groups. Patients referred by their general practitioners, and patients attending hospital, give a relatively high yield of positive findings, and it is often useful to radiograph the work group of a patient newly diagnosed at a chest clinic. Similarly the

appearance of several cases in one village is a good argument for a survey of the whole population by radiography and skin testing. The Ministry also holds that all pregnant women should be radiographed as part of routine antenatal care.

In short it believes that the M.O.H., the chest physician, the family doctor, and the mass-radiography unit, working together and consulting often, can apply the traditional methods of epidemiology, and the newer techniques of radiology and skin testing, to the detection of the epidemic pattern of tuberculosis in their area. It is particularly important, the memorandum adds, that the general practitioner should be fully informed about what is going on; for without his support the campaign cannot succeed: and indeed its complete success depends on the active collaboration of everyone concerned in the detective work.

The Sardinian Campaign

In 1945, when the destructive consumption of war mercifully ceased, the Allied nations diverted their geared-up production and surplus stores to beneficent uses under the direction of UNRRA; in addition, the United States provided dollars to aid recovery in Europe under E.R.P. In the Italian sphere the first call on these materials and funds was for emergency work, such as controlling malaria and other epidemic diseases. But members of the UNRRA mission were anxious to invest some of the funds in work of lasting value. Dr. F. L. SOPER, of the Rockefeller Foundation, proposed a mosquito eradication campaign; and Sardinia was chosen because, being an island, it is a relatively isolated unit and because it was the most malarious part of Italy. Members of the Rockefeller International Health Division had behind them successful eradication campaigns in Brazil and Egypt. They had established that, at least in some circumstances, extensive and vigorous eradication work could obviate the trouble and expense of routine control measures. With this background, it was intended to plunge directly into a similar campaign in Sardinia, relying on administrative experience gained in earlier schemes and on existing knowledge of the Sardinian malaria vector, *Anopheles labranchiae*.

In October, 1945, UNRRA agreed in principle to the project, which was to be carried out jointly by the Italian government, UNRRA, and the Rockefeller Foundation (which supplied technical staff and extra funds). A special agency known as ERLAAS (Ente Regionale per la Lotta Anti-Anofelica in Sardegna) was set up to conduct the campaign. Delays in assembling staff and equipment deferred the start of eradication work until early in 1947; but this was no misfortune, since it gave time for a survey of the island by a malariologist and an entomologist. By 1947 it was realised that this campaign, aimed at the extermination of indigenous mosquitoes, would be much more difficult than the earlier campaigns, which had dealt with mosquitoes intruding into new territory. Furthermore, the Brazilian schemes had attacked highly domestic strains of mosquitoes which were never found breeding far from man; whereas *A. labranchiae*, though a man-biter, will readily breed in remote places and feed on wild animals. To offset these difficulties, there was the new weapon of

3. Circular 22/53.

4. Memorandum 324/B.C.G.

dicophane (D.D.T.), for attacking both larval and adult mosquitoes. Dicophane house-spraying programmes had substantially reduced malaria in continental Italy and elsewhere; but in these regions the behaviour of the anopheline vectors was very different from that of *A. labranthiae* in Sardinia. Thus, in the potentially malarious Roman Campagna this mosquito inhabits a relatively crowded agricultural area. The adults readily enter houses to feed and rest, and a high proportion of the mosquito population soon encounters dicophane. In Sardinia, on the other hand, the people live in few compact villages surrounded by wild territory; and most of the adult mosquitoes rest in caves and other natural shelters, safe from residues of dicophane. Accordingly, though the campaign against *A. labranthiae* in Sardinia included several island-wide house-spraying operations, the main attack consisted in tracing and treating all breeding-places; and in 1948 this attack was extended throughout the island. When it was found that many breeding-places were inaccessible, an enormous army of workmen, numbering up to 30,000, was recruited to clear vegetation and drain swamps so that the 6000 larviciders could treat all sites. A large force of scouts was employed to check the work. Despite all this effort, positive foci of *A. labranthiae* were found in many places in 1949, and attempts were made to eliminate these by vigorous local attacks. Yet almost as many breeding-sites were discovered in 1950, and when the campaign

finally closed in the autumn of that year it had failed in its object.

An ill-natured or ill-informed critic might dwell on the fact that, over a period of four and a half years, some 6700 million lire (about £3 million) had been spent without achieving eradication. But a great deal has been gained; for whereas in 1946 there were 10,000 primary cases of malaria and 75,000 relapses, the disease is now reduced to the vanishing-point. This is no mean gain; for the disease, as well as impairing the health of Sardinians, hindered colonisation of their under-developed island. Perhaps malaria could have been eliminated more cheaply; but in 1945 eradication of the mosquito seemed feasible, and no-one could then predict the outcome. It now seems probable that *A. labranthiae* cannot be exterminated without quite disproportionate effort and expense, and the Organisation were wise to cut their losses and stop in 1950. The final act of the Rockefeller Foundation has been to produce an account of the campaign, written by Dr. LOGAN,¹ who directed the work for most of the period. It is well that the lessons so hardly learned should be on record, for guidance of the many further anti-mosquito programmes that are afoot.

1. The Sardinian Project: An Experiment in the Eradication of an Indigenous Malarious Vector. By JOHN A. LOGAN, with the collaboration of Thomas H. G. Aitken, Guido V. Casini, Frederick W. Knipe, John Maier, and Athol J. Patterson. Baltimore: Johns Hopkins Press. 1953. Pp. 415.

Annotations

CHOLECYSTOGRAPHY AND CHOLANGIOGRAPHY

SINCE cholecystography was introduced by Graham and Cole in 1924, the radiographic examination of the gall-bladder with opaque media has been a routine and invaluable aid to the clinician in the diagnosis of gall-bladder disease. The contrast medium first used—tetrabromphenolphthalein—was soon replaced by the corresponding iodine derivative. Administration was at first intravenous, but later the oral route was adopted to avoid the systemic reactions which occasionally followed injection into a vein and the danger of sloughing of tissue from inadvertent local injection into the tissues. For some time there was doubt about the significance of failure to obtain any gall-bladder shadow. Experience, however, proved that the radiological finding of a "non-functioning gall-bladder" was fairly reliable evidence of disease; and Gordon¹ concludes that this finding is significant in about 94% of cases. Such a degree of reliability compares favourably with that of many other investigations which we regard as valuable.

In 1940 Dohrn and Diedrich² introduced an iodine-containing derivative of phenylpropionic acid which has been widely used (as pheniodol). It has the advantages that reactions to its oral administration are less common and absorption is more consistent. Moreover, since it is freely excreted also by the kidneys, it can be given without danger to patients with impaired liver function or even jaundice. Latterly it has been claimed that 'Telepaque,' a derivative of ethylpropanoic acid, causes even less alimentary upset and gives a denser shadow because its iodine content (66%) is 15% greater than that of pheniodol.³

The usefulness of these media depends on their concentration in the gall-bladder. They do not permit distinction between obstruction of the cystic duct and

failure of concentration due to disease of the gall-bladder wall; and they do not display the bile-ducts except in the rare event of radiography coinciding with the secondary filling of the ducts with concentrated dye from the contracting gall-bladder. What is required is a substance that will display the biliary passages without concentration in the gall-bladder. This property is claimed for a new agent, 'Biligradin Intravenous,' which is the disodium salt of adipic-di-(3-carboxy-2:4:6-triiodo-anilide). It contains 64% of iodine, and after intravenous injection is excreted so rapidly into the bile-ducts that these are shown on radiographs taken 20–30 minutes after injection. The gall-bladder fills more slowly and is seen on films exposed about 2 hours after the injection. The practicability of cholangiography with biligradin intravenous is confirmed by Hornykiewytch and Stender,⁴ Pahl,⁵ and other German workers. It is said to be well tolerated when injected intravenously; accidental paravenous injection results in transient burning pain but no necrosis of tissue. The extrahepatic and even the intrahepatic ducts are nearly always shown, provided liver function is not seriously impaired and the sphincter of Oddi is competent; stones in the common duct are demonstrated even with jaundice of recent onset.

If these claims are confirmed, biligradin intravenous should prove most valuable in the investigation of diseases of the biliary tract. It may prove particularly useful in the diagnosis of functional disturbances of the biliary tract both before and after cholecystectomy.

ANÆSTHETIC EXPLOSIONS

THE Ministry of Health's Working Party on Anæsthetic Explosions is expected to report soon on its investigations and to propose lines of research. Meanwhile Dr. Bullough describes on p. 798 of this issue a method of preventing the collection of explosive gases in the theatre by withdrawing them into the outer air. This method, which calls for a leakproof apparatus, does not reduce the risk of

explosion arising within the anæsthetic machine; but it will, as Dr. Bullough suggests, prevent explosions caused by ignition of a pool of gases outside the machine. A not inconsiderable advantage of Dr. Bullough's arrangement is greater purity of the theatre atmosphere. At the end of a long day anæsthetists, despite their acquired tolerance, are sometimes more noticeably sedated than at the outset.

In this week's issue of the *British Medical Journal*, Dr. J. G. Bourne draws attention to a danger of cyclopropane anæsthesia for dental extractions. A spark may be given off when forceps slip on a tooth; and Dr. Bourne finds that after administration of a mixture of 50% cyclopropane and 50% oxygen, the expired gases may be ignited by a spark up to the sixth exhalation after the anæsthetic is withdrawn. Cyclopropane, he says, should not at present be used for dental extractions.

CONTROL OF TRICHINOSIS

FROM time to time outbreaks of trichinosis in Britain draw renewed attention to the need for improved control of this serious and not infrequently fatal disease. Man is infected by eating trichinosed pork, while the pig is thought to become infected usually by eating scraps of raw pork. In other countries certain other mammals have recently been shown to spread the disease; in Germany fox trichinosis is apparently widespread, and cases in domestic pigs may largely arise from ingestion of infected fox flesh. During a series of outbreaks of trichinosis in Greenland in 1947, examination of muscles of the mammalian fauna showed that nearly 70% of the sledge dogs and about 30% of the Polar bears were infected.

One way of countering the risk of trichinosis in man is to examine samples of the muscle of all carcasses of pork slaughtered for human consumption; and this method is followed routinely in Germany, Denmark, and other Continental countries. In British abattoirs no such routine examination is made; but isolated examinations from time to time have suggested that the prevalence of the disease in the pig population is low. In the U.S.A., on the other hand, trichinosis is a serious problem. Gould et al.¹ believe that, as a result of eating trichinosed pork, "about 25% of all Americans during their lifetime will harbour parasites in their muscles"; and 1.5% of the pigs slaughtered are infected with trichinosis. Only a small proportion of the pork is processed, under government regulations, by heating, freezing, or other methods.

Gould et al. have now described their investigations into gamma radiation of raw pork as a method of controlling the disease. They find that a dose of gamma radiation of Co⁶⁰ applied to infected raw pork will render sterile any adult worms which may develop in man's intestine after a meal of such pork, while a slightly larger dose will render the encysted larvæ in the pork non-viable and prevent their development into adult forms. A preliminary study of irradiation with waste fission material contained in old nuclear fuel rods suggests that this may prove a suitable substitute for Co⁶⁰. It seems that the flavour of pork exposed to irradiation is unaffected, and no known harmful effect would ensue in a person who consumed it.

Further research on these lines will be followed with interest in this country, for the lack of data on the prevalence of the disease in our indigenous pig population must cause some concern. This gap should be filled by a country-wide survey. Another measure which would commend itself to public-health authorities is intensive propaganda drawing attention to the danger of pork products—particularly sausage—unless these are thoroughly cooked before they are consumed.

PERIPHERAL ARTERIAL EMBOLISM

THE events that follow impaction of an embolus in a peripheral artery are fairly clear. The soft mass of blood-clot is subjected, after its initial arrest, to the hammer-like blows of the pulse wave, which may cause its disintegration and further migration. Where the embolus is finally impacted the artery may be moderately distended, with reactive œdema and cellular infiltration in its wall. Shepherd¹ has shown that occlusion of the femoral artery over a short segment caused a sharp fall of intraluminal pressure distal to the block, but that, owing to the collateral circulation, within a few minutes the peripheral blood-flow approximates to a normal resting level, although the amplitude of the pulse wave is impaired.

After embolic occlusion the expected restoration of blood-flow through collateral channels may not occur. The reason for this has been much debated; and Richards² has marshalled much of the evidence in a review of 52 closely studied patients. The patient with a severe cardiac lesion may not have a high enough blood-pressure effectively to open up collateral circulation. Moreover the embolus may lodge at a bifurcation, such as the division of the femoral artery, obstructing both the main vessel and the major collateral pathway. Some³⁻⁵ believe that widespread arterial spasm, such as develops in traumatic lesions,⁶ follows lodgment of an embolus. But many would agree with Pickering⁷ that the idea of "vascular spasm, occurring in the absence of a recognisable stimulus is entertained too freely and uncritically in current thought and writing." The diminution in arterial diameter distal to the occlusion is probably quite often due to diminished arterial pressure; and Burton⁸ suggests that blood-vessels, being distensible tubes, have a "critical closing pressure." Thrombosis probably always extends beyond the site of embolism.

Richards concludes that the clinical onset of embolic impaction is usually sudden and dramatic. Pain, if present, is of two types: an initial pain most severe at the onset and localised to the site of embolic occlusion; and a delayed ischæmic pain felt more peripherally, which becomes so intense that it dominates the clinical picture. Absence of peripheral pulses, changes in colour and temperature of the skin, and muscle and nerve lesions are evident on examination.

Enthusiasm for embolectomy has decreased in recent years.⁹ Collective results published by Strömbeck¹⁰ showed that two-thirds of patients so treated died in hospital, and only 19% were discharged with adequate circulation in the affected limb. The case for embolectomy is perhaps strongest where the embolus straddles the aortic bifurcation. Milwidsky et al.¹¹ state that most patients with an embolus at this point die from shock or heart-failure shortly after the onset of symptoms, and those who survive the first day usually die from limb gangrene and infection. Albright and Leonard¹² cited 26 reported cases in which an aortic saddle embolus had been successfully removed by embolectomy. Milwidsky et al.,¹¹ however, describe 2 cases in which the patients

recovered with conservative therapy; and such experience is probably not exceptional. In the arteries of the arm and the smaller peripheral arteries of the leg embolectomy has no place. Richards² agrees with Veal and Dugan¹³ that embolectomy is indicated when the embolus has lodged in the femoral arteries if conservative measures have not brought about distinct improvement within a few hours. Under conservative treatment morphine is given for the relief of pain, and the leg is kept horizontal in an environmental temperature of 20°–25°C. The body is warmed by a heat cradle or electric blanket, in an attempt to open up the peripheral circulation; and sympathetic constrictor fibres are interrupted by a paravertebral block of procaine hydrochloride or 8% phenol. Heparin should be given, to control secondary extension of the thrombus. There seems to be no advantage in intra-arterial injection of vasodilator drugs. Should both patient and limb survive—as in 24 of Richards's 52 cases—symptoms of arterial deficiency ensue. Claudication, nerve palsies, and nutritional changes are common, and few patients are symptom-free.

The correct treatment for peripheral embolism is still undecided. For a balanced evaluation it is important that further well-documented series like that of Richards—and not only reports of cases successfully treated—should be published.

OXFORD UNIVERSITY AND THE RADCLIFFE

THE future of the clinical medical school at Oxford is again under discussion. Ever since the establishment some twenty years ago of the Nuffield professorial units at the Radcliffe Infirmary, the practical service of a large county hospital has been supplemented by these specialised departments to which postgraduates from all over the world have come for training. These units have worked out their respective spheres of action more or less amicably with the established services, but a difficulty here as elsewhere has been the scarcity of beds. After the late war the Radcliffe Infirmary developed from a large county hospital to become the centre of the regional hospital organisation under the National Health Service.

In 1939 the teaching facilities in the Radcliffe were extended to allow for a complete medical course to be taken in Oxford, and in 1943 in the Goodenough report Oxford was envisaged as a small medical school of carefully selected students, taught under the tutorial system, the stress lying on the scientific aspects of medicine. On this suggestion medical opinion in the university is sharply divided: some feel that the pre-clinical and clinical departments could work closely together to this end, while others favour a wider training for a putative specialist, and doubt (as we do) whether he should be selected so early in his career. Certainly the clinical school will have to attract a number of candidates of a high intellectual calibre, which may not be easy for a young school competing with the prestige of the older hospitals in both medicine and sport.

Oxford University has now written to the Minister of Health asking for a controlling voice in the management of the Radcliffe Infirmary, so that it can develop as a teaching school on the lines of the Goodenough report, with the Nuffield professors of medicine, surgery, and obstetrics and gynaecology in full control of their departments, as regards finance, appointments, beds, and laboratory space. On this plan cases deemed unsuitable for teaching would presumably be admitted to such hospitals as the Churchill, a munificent present from the American Armed Forces to the City of Oxford. At present the allocation of cases between the two depends both on the facilities available and on their relative sites, the Churchill standing high above Oxford on the slopes of Shotover; and an artificial division of ill people into

teaching or non-teaching cases would not be universally approved. The university says that its dissatisfaction with the present teaching arrangements was apparent to the hospital board when an application for the quinquennial grant was made in 1951 to the University Grants Committee; but the board state that they have never been informed exactly what changes the university desires in the teaching facilities, and express regret that they were not asked to comment on this letter to the Ministry until after the decision had been taken to send it. They are clearly anxious to fulfil their two great responsibilities in the Radcliffe Infirmary—to keep up its great tradition of service to the surrounding district, and to contain a thriving young medical school backed by the old-established preclinical departments. We should expect from Oxford a statesmanlike solution to this problem.

EGGS AND RHEUMATIC FEVER

Few would now dispute that infection with β -haemolytic streptococci plays an important part in the aetiology of rheumatic fever; but the absence of these organisms from the rheumatic lesions themselves has led to the view that the true cause is some circulating toxic product of the organism; and since a first attack of rheumatic fever does not usually become manifest until 2–3 weeks after the streptococcal infection, the rheumatic lesions are usually regarded as the result, not of direct action of streptococcal toxin, but of an allergic reaction between the toxin and its specific antibody.

In epidemics of streptococcal sore throat, the incidence of rheumatic fever is usually about 3%.¹ Apart from some genetic predisposition little is known of the factors that lead to this complication. Nutrition has long been regarded as a possibly important factor, especially as the incidence of the disease is higher in the poorer members of the community. Coburn² showed that a supplement of egg-yolk powder equivalent to 8 eggs per day apparently had a significant protective effect in a small group of children known to be susceptible to rheumatic relapse after a streptococcal infection. Moreover, of 14 rheumatic children of wealthy families, only 1 ate a normal diet and 10 did not eat eggs at all. The mechanism of this protection was obscure, but Coburn was inclined to associate it with the rise in the serum-cholesterol level induced by eggs.

Wallis³ has again drawn attention to the apparent protection afforded by this food. His evidence is based on the results of questioning 184 patients with rheumatic heart-disease and 1380 normal controls. Despite the undoubted errors that must mar such an investigation, the results are suggestive. 40.6% of all the cardiac patients asserted that they ate few eggs in childhood, and 10.2% expressed dislike for eggs; the comparable figures in the control group were 16.3% and 4.6%. In an attempt to explain this observation, Wallis and Viergiver⁴ concentrate particularly on the level of the serum inhibitor of the serum extractable haemolysis of β -haemolytic streptococci—the so-called streptolysin S. It is now established that this naturally occurring inhibitor is, or is closely related to, plasma-phospholipid, and Wallis and Viergiver seek to correlate the protective value of eggs with their stimulating effect on plasma-phospholipid synthesis. They rightly point out that choline, an essential constituent of most of these phospholipids, is present in unusually rich amounts in egg-yolk; but they err in classing choline among the indispensable dietary constituents, since the body can readily synthesise all the choline it requires provided the intake of labile methyl

groups from other sources (e.g., methionine) is adequate. That choline is not deficient in rheumatic fever is confirmed by the absence of any signs of undue fat accumulation in the liver of patients with the disease. Furthermore, dietary deficiency of choline, while certainly affecting the phospholipid turnover in the liver, may nevertheless be associated with a rise in the plasma-phospholipids secondary to diminished intrahepatic utilisation.^{5 6} Since, therefore, there is no real evidence that a diet deficient in eggs leads to deficiency of plasma-phospholipid, and hence of the serum inhibitor of streptolysin S, and since, moreover, there is no experimental evidence that this lysin produces any lesions resembling those of rheumatic fever,⁷ the protection, if any, afforded by eggs cannot be explained on Wallis's hypothesis.

THE FEVER NURSE

THE General Nursing Council's proposal to ask the Minister of Health to close the infectious-diseases register has disquieted both doctors and matrons, who predicted that such a step would gravely damage the service.⁸ The Minister of Health has now decided that the obligations of the council to maintain the register and to provide for admissions to it are to "remain in force for the time being."⁹

The G.N.C. suggested that training for the register was often unsatisfactory because of dearth of clinical material; and that, many of the training-schools being small, the services of sister-tutors were being used uneconomically. The council believed that the fever register might be discontinued without detriment, provided that suitable infectious-diseases hospitals were included in group schemes of training for the general part of the register. The Minister, though refusing to accept the council's proposal, is impressed by its reasoning. Training for the fever register, he says, should be concentrated in the larger units, and the smaller units should abandon the attempt to provide this training. Small hospitals are advised to take one or other of the following courses:

(a) To seek to become part of a group training-school training nurses for the general register.

(b) To seek approval as training-schools for assistant nurses in association with other suitable hospitals.

(c) To form their nursing establishment on the basis of a nucleus of registered fever nurses assisted by enrolled assistant nurses and/or nursing auxiliaries.

In the Minister's view the needs of the infectious-diseases hospitals for specially trained staff can best be met by general-trained nurses with additional training and experience. Such nurses can be admitted to the fever register after a year's post-registration training; but the G.N.C. has approved several experimental courses of training whereby general-trained nurses can qualify for admission to the fever register after nine months' additional training. The council is also ready to consider approving experimental courses of integrated training for admission to both the general and the infectious-diseases parts of the register.

The Ministry strongly advises the management committees of the hospitals which continue to train for the infectious-diseases register to try to attract general-trained nurses to take the special training; and to give such applicants preference over untrained applicants seeking to take the two-year course. It would be interesting to know, however, in what the attraction is to consist. The vulgar subject of money is not mentioned in this circular; but the fact remains that a general-trained nurse who seeks a further qualification in infectious

diseases drops, on starting, some £15 per annum on the salary she has been getting as a staff nurse in a general hospital—a somewhat negative attraction.

HÆMOLYSIS AND ECLAMPSIA

Pritchard et al.¹ have described three cases of eclampsia complicated by severe intravascular hæmolytic, thrombocytopenia, and deficiency of some clotting factor which was present in fresh normal plasma. Plasma-fibrinogen levels were normal; the patients' blood contained no auto-agglutinins or hæmolytic factors, and in only one case was there rhesus incompatibility with positive direct and indirect Coombs tests. Corticotrophin (A.C.T.H.) was given to each of these patients, and in two, who died, the platelet-counts increased; but in the third, who survived, the platelets increased spontaneously, and Pritchard et al. believe that corticotrophin did not influence the course of the disease.

Although pigment casts are found in the collecting tubules of the kidney in fatal eclampsia,² such gross hæmolytic episodes as those described by Pritchard et al. are uncommon. Young and McMichael³ described the "crush syndrome" in two women who had difficult labours; and Young⁴ reported several such cases, from which he concluded that this syndrome arose in obstetrics only with trauma to the maternal tissues or premature separation of the placenta. Paxson et al.⁵ reported a case of eclampsia with clinical and pathological features of this type.

Clotting defects due to fibrinogenopenia, and histological changes superficially similar to those of toxæmia of pregnancy, have been induced in animals by injections of thromboplastin⁶ and trauma to the placenta⁷; and fibrinogenopenia has been demonstrated in patients with eclampsia and retroplacental hæmatomas,⁸ in whom incidentally the plasma showed traces of hæmolytic factors. Although fibrinogenopenia was not a feature in Pritchard's cases a derangement of normal hæmostasis, which was not fully understood, was detected in both series, and a common ætiology may reasonably be suspected. Pritchard and his colleagues conclude that some immunological reaction was responsible for the condition they describe; and, if it cannot be explained in terms of the crush syndrome, at least the trend of their thought is shared by another group, who have likened the manifestations of eclampsia to a generalised Shwartzman phenomenon.⁹

Dr. J. GREENWOOD WILSON has been appointed medical officer of health of the Port of London.

THE MENTAL HEALTH OF
UNDERGRADUATES IN ENGLAND

A report on the first 18 months of a psychiatric service for students at the London School of Economics.

J. C. READ
M.R.C.S.

RESEARCH ASSISTANT, INSTITUTE OF PSYCHIATRY, UNIVERSITY OF LONDON

In the major American universities the mental health of the students has for some years had systematic attention. The fullest reports have come from Yale and Michigan. In 1942 Fry and Rostow² gave a very readable account of a decade's experience at Yale, and Raphael³⁻¹³ has provided data of all kinds on the mental health of the students at Michigan University since the opening of a full-time service in 1930. Other valuable papers have come from Harvard,¹⁸ Minnesota,⁴ Oakland,¹⁴ and some of the medical schools.^{5 15 16 20} But in this country little information has been available. Parnell in 1947 drew attention to his finding at routine examinations that minor psychological disturbances are common⁷; but more interest was generally taken in his indictment in 1951 of mental illness as the most important cause of a loss of a term or more of residence at Oxford.⁸ A similar finding in a report for 1949-50 made to the University of Wales was noted by the *British Medical Journal*,¹ and *The Lancet*⁶ drew attention to Macklin's two-year study at Aberdeen which pointed out the bad effect of an overfilled curriculum. Other annotations in 1951 in both these journals refer to the unusual strains of undergraduate life and their effect on mental health. In the same year Verney¹⁹ commented on the influence of National Service on Edinburgh medical students, and Swainson¹⁷ described a project carried out by a lay therapist at University College, Leicester. But very little on the subject has appeared since then.

At the third Conference on Student Health in British Universities and Medical Schools, held under the auspices of the Nuffield Provincial Hospitals Trust at Cambridge in 1951, mental health was a good deal discussed. Of the many papers presented at that gathering the only one published is that of Henn,³ dealing with failure in examinations; but the privately circulated transcripts contained much interesting material and showed that at various universities special provision had been made for students needing psychiatric help. In London, however, little had been done except at University College, where psychiatric advice was provided by the student health centre.

AN EXPERIMENTAL SERVICE

In January, 1952, on the initiative of the Institute of Psychiatry, an experimental psychiatric service was established for students of the London School of Economics.

At this school there is no routine medical examination of new students, and it was thought inexpedient to try to discover the prevalence of nervous troubles by circulating questionnaires. To find out who would come for psychiatric advice, and for what kind of problem, a purely clinical approach seemed to be the right one. The only publicity given to the service, to launch it, was a meeting between the students' welfare committee and the psychiatrist, and a letter sent individually to the students inviting them to come for consultation if they were worried about their work or their personal life. The confidential nature of the service was emphasised, and the fact that no fees would be payable. The staff, also, were informed by letter of the purpose of the service.

The plan was to interview all who sought advice, and, after making sure they were not already in a doctor's hands, to take as complete a history as possible and, where it seemed proper, undertake treatment. It was arranged that in cases of serious breakdown the patient could be referred to the Maudsley Hospital. Six sessions weekly were held at the school, but those who preferred greater privacy could be seen at other times at the Institute of Psychiatry.

During the remainder of the 1951-52 session, 68 students came for advice and treatment. In the 1952-53 session, 63 new cases presented themselves. Thus the total for the whole period from Jan. 24, 1952, to June 30, 1953, was 131. Of these, in the first session 64 were full-time students (out of a total of 1743), and 4 were part-time students (out of a total of 402). In the second session 59 were full-time students (out of a total of 1753), and 4 part-time (out of a total of 434). 20 students first seen in 1951-52 were carried into 1952-53 which made the total dealt with in this session 83.

Because so many attended, patients were rarely seen more frequently than once a week. The usual length of an interview was fifty minutes, but the first usually lasted an hour. The number of times any one student was seen varied between 1 and 53, the average being 9. Ages ranged between 18 and 40 years (average 24½).

DIAGNOSES

The diagnoses were:

1. SEVERE CASES		
Affective breakdown	3
Mixed depression and anxiety	3
Acute anxiety attacks	3
Chronic anxiety state	3
Anxiety with disorder of physical function	2
Mixed anxiety and obsessional state	1
Obsessional state	3
Hypochondriasis	1
Conversion hysteria	1
Personality disturbances with marked social consequences	7
		<hr/> 27
2. MODERATE CASES		
Depression	3
Anxiety state	3
Anxiety with disorder of physical function	6
Emotional outbursts	2
Hypochondriasis	2
Asthma and dermatitis	1
Paranoid state	2
Obsessional state	3
Speech difficulties	2
Personality disturbances (inferiority feelings, study difficulties, &c.)	12
Marital and other family problems	4
Psychosexual difficulties	5
		<hr/> 44
3. MILD CASES		
Depression	4
Anxiety state	8
Emotional outbursts	3
Obsessional state	2
Hypochondriasis	2
Physical symptoms of functional origin	5
Personality disturbances (inferiority feelings, study difficulties, &c.)	17
Marital and family problems	7
Psychosexual difficulties	9
Other problems	3
		<hr/> 60

The allocation of these cases to one of the three categories of severity is necessarily imprecise. It depends either on the acuteness of the disturbance at first presentation or the degree to which the patient's nervous condition affected his social adjustment.

As examples of those put into the first group may be cited students with affective disorders who needed hospital care, those suffering from acute anxiety attacks so severe that they were physically ill, and those whose symptoms were so severe that it was obvious to their

teachers that they needed treatment and perhaps advice whether or not to continue with their studies. 11 of the patients allotted to this group had had psychiatric advice on some previous occasion and 5 of them had had frank breakdowns.

The patients placed in the second category are those whose symptoms were evidence of a considerable degree of disturbance but whose social adjustment was good enough for their distress to have remained to a large extent a private matter. In this group perhaps the clearest signs of improvement due to treatment are shown.

The third group is similar to the second but milder.

RESULTS

The table shows the result of treatment in those who came for more than one interview.

RESULTS OF TREATMENT

Category	Case complete or student left L.S.E.	Still having treatment
Severe :		
Much improved	4	1
Some improvement	7	8
No change	1	2
Moderate :		
Much improved	5	2
Some improvement	10	8
No change	11	7
Mild :		
Much improved	16	—
Some improvement	12	1
No change	8	2
Total :		
Much improved	25	3
Some improvement	29	17
No change	20	11

11 students terminated their treatment by default.

In 53 cases the emotional disturbance was affecting the student's studies in an obvious manner; in 15 of these treatment led to a definite improvement in this respect.

The therapeutic effects of the clinic are difficult to assess with any accuracy. So much else goes on in the lives of students, and so many of them are at a period of great change in their personal development, that such evaluations are even more hazardous than with the average series of results of psychotherapy. It can, however, be said that their symptoms improve and that the students connect this with their interviews and themselves suggest discontinuing as soon as they feel fit to do so.

The diagnoses of the 12 cases in the first two groups which showed a marked improvement are :

Acute anxiety attacks	3
Anxiety state	1
Anxiety with disorder of physical function	2
Obsessional state	2
Hypochondriasis	1
Personality disturbance affecting relations with others	2
Personality disturbance mainly revealed in study difficulty	1

To achieve this improvement the various types of anxiety required between 5 and 37 interviews; obsessional states 13 and 20; the case of hypochondriasis 30, and the personality disturbances 15, 23, and 41.

An effort was made to make the clinic self-contained and not to regard it as a stepping-stone on the way to treatment elsewhere, except for the few patients who were ill enough to need hospital care. Treatment at weekly intervals is not intensive, but patients of this age and intelligence seem definitely able to benefit from it. It is an advantage that the small amount of time

required interferes little with other commitments, an important consideration in view of the fullness of the present-day undergraduate time-table.

That the students in the first two groups can be successfully dealt with in such circumstances goes far to justify such a clinic as this; and there is reason to believe that some of them might have hesitated dangerously to seek help if it had been more difficult to obtain. All those in the third group, whose condition might be described as a neurotic reaction to a situation of temporary strain, would hardly be accepted for treatment elsewhere and yet undoubtedly need help. The undergraduate is living under conditions of special strain—intellectual, financial, and cultural. The healthy student will withstand this strain and may even benefit from it, but the more vulnerable individual gives way and begins to exhibit weaknesses and abnormalities which in less exacting circumstances would have remained latent. Such in varying degree is the situation of the students whose cases are enumerated above.

These emotional disturbances, unless severe, may pass unrecognised. This is illustrated to some extent by the fact that only 27 of the 131 students came for advice at the suggestion of their teachers; in the remainder there were only 20 of whom it could be gathered from the school records that they were in any way unstable. A psychiatric service of this kind permits the quickest contact and disposal for the severe cases, and the others have assistance which they would not find easy to obtain elsewhere.

CONCLUSION

From this eighteen months' experience it is clear that a service of this kind at a school or university has great advantages: teachers and administrators find it helpful to have a close contact with a psychiatrist in the case of need; and there is no doubt that students are prepared to seek advice when they feel themselves to be emotionally disturbed. None come frivolously and few show any inclination to prolong their attendance unduly: they have too much else to do. As they have the insight to seek help and the ability to use it when it is provided, a psychiatric service for students appears to meet a real need and deserves to become an integral part of a university school. It is justified by the immediate gain for certain students and the probable good effect on their future well-being; and over a number of years such a service would be a valuable source of information about the mental health of the community, because of the high intelligence and ability to communicate of its patients, who are drawn from a very wide range of the population.

Thanks are due first and foremost to Prof. Aubrey Lewis, of the Institute of Psychiatry, who conceived the idea of this service, gave it the opportunity to develop, and has supported it throughout with his advice and kindness; to the Board of Governors of Bethlem Royal Hospital and the Maudsley Hospital for financial support; and also to Sir Alexander Carr-Saunders, and the staff and students of the London School of Economics, for their hospitality to the experiment and their co-operation in running it.

THE DISTRESSED STUDENT

NICOLAS MALLESON

M.B. Camb., M.R.C.P.

PHYSICIAN IN CHARGE OF STUDENT HEALTH ASSOCIATION,
UNIVERSITY COLLEGE, LONDON

THE occupational hazards of a student are principally psychiatric. In its most specialised aspect, the work of a doctor in charge of a student health service concerns mental distress. Recently in this country there has been a considerable amount of publicity about mental ill health in the universities, and in particular about its tragic highlight—suicide. A general discussion of the topic may, therefore, be in order.

THE SIZE OF THE PROBLEM

How prevalent is student distress? What, in the unsatisfactory analogy of disease, is the morbidity-rate? It is almost impossible to answer this; for, except by an objective and dramatic action, like abandoning an examination, assaulting a professor, or committing suicide, the student only registers his distress if he comes and tells you. By no means all distressed people tell their troubles to others. Even when they do, it may not be to the university physician, but to a friend, or an academic supervisor, or even a doctor outside. Their unhappiness is then statistically non-existent. Again, the degree of distress which a person will suffer before coming to the consulting-room varies greatly. In America, where psychiatry is respectable almost to the point of being de rigueur, the number of people going to psychiatrists is higher than in this country, but one would hesitate to conclude that the sufferings are greater. At Oxford Parnell¹ was able to trace 9 suicides among 18,500 student years, whereas at University College, London, I am able to find only 2 suicides in 12,000 student years. Even as a Cambridge man, I find it hard to believe that the differences are due to the more heinous conditions at Oxford. They must reflect differences in the students' cultural backgrounds. Despite the difficulties, one must try to compose some sort of estimates.

At University College, London, there are about 2800 full-time students and about 600 part-time. Only a small proportion of the part-timers are likely to use the health service, so it might be fair to say the population at risk is about 3000. About 75 new cases of distress present themselves every year. Assuming an average stay at college of three years, there would be 225 students who had suffered, were suffering, or were going to suffer distress that would bring them to the consulting-rooms. This would represent something like 7½% of the total population. About half the students come from homes in the London area and live at home during their course; about half of these apparently do not use the health service. It seems probable that if, and when, they suffer distress and seek help, they go to their family doctor, or perhaps their priest, rather than come to us. If these few are included in our estimate, the prevalence goes up to 10%.

It is difficult to compare this estimate with the incidence of distress in other institutions because circumstances are

always different. In the University of Michigan, which has a well-developed mental-hygiene service, 10% of the student body—the same proportion—had sought help at one time or another during their course. Most other American mental-health services have a similar attendance. In England comparisons are more difficult, but most of my colleagues would accept this general estimate. The round figure of 10%, then, is probably as close as one can get. It is a considerable figure and in practice must have considerable implications.

In this country, about 10% of the students who start at university do not finish the course. Most of these failures occur at the end of the first or second year. A small number repeatedly fail their final examinations. Since everyone who comes to university has presumably shown adequate intellectual ability in the entrance examinations, it seems more than probable that distress, as one meets it clinically, is a major element in this failure.

THE QUALITY OF THE PROBLEM

Psychiatric classification is an inaccurate necessity. The following has a rough utility:

Serious mental illness.—In this group are the psychoses (of which schizophrenia is far and away the most common), the melancholias, the confusional states, and those psychoneurotic disturbances that are so severe as to constitute an almost total disability. At University College over the last four years about 5% of distressed students fall into this category. In general this tallies with figures from many American universities and is similar to figures from other English universities.

Severe adjustment problems.—This empirical category covers those cases where distress is a major obstacle to the student's university career or personal happiness. Dealing with his distress is, therefore, his primary concern, for it compromises the possibilities of university success. Most of the students in this category have a definitely psychoneurotic personality and my clinical impression is that they will suffer psychiatric symptoms off and on throughout their life. At University College, about 30% of the distressed students can be classified here.

Mild adjustment problems.—In this equally empirical category are all those students who suffer distress which is a disability to them, yet not one of overriding severity. Such people may be successful in the university, both in their examinations and in their social life. Nevertheless, they are suffering unhappiness, and usually some diminished efficiency, and they come to the consulting-room in the hope of amelioration. At University College about half of the distressed students belong to this group.

Miscellaneous.—One is left, as always, with a mixed bag of cases—i.e., those referred by the departments for administrative reasons, and so forth.

HOW THE DOCTOR CAN HELP

For the university physician, the severe cases, paradoxically enough, are fairly easy to manage. Treatment is primarily for the qualified psychiatrist and it almost always involves interruption of studies and admission to hospital. It is the adjustment problems, serious or mild, that are the headache of university practice. Not only are they numerically the greatest, but their management, as a rule, falls to the physician himself.

The first step is to take a full *history*. This must cover not only such obvious things as the family relationships, social life, sexual life, and previous periods of unhappiness, but it must also go thoroughly into the student's academic record, his way of work, his hours of work, and all his particular studying difficulties. If there is any question in the patient's mind as to whether there could be any physical basis to his symptoms, a full medical examination must be undertaken. In my view, this full know-

ledge of the patient, and the personal rapport that is made in getting it, is the basis of effective help.

The simplest help one can give is by medication. A little judicious sedation with the ordinary barbiturates is a relief to most unhappy people. Sometimes a stimulant is more effective. Occasionally something a little more bizarre is indicated. Doubtless the psychological effect of bottles and pills is often as important as the pharmacological—no matter, it helps. All clinical work is empirical.

Advice is next in the clinical armamentarium. Simple study advice is often needed. Many students, particularly anxious students, overwork themselves greatly. They study till late at night, and when exhaustion impairs their efficiency they are overcome by mortifications and anxiety. If one can impress them sufficiently with one's own confidence, they may be prevailed upon to work more regular hours and stop before the point of tiredness. They may be persuaded to take up games or other social activities which, in their anxiety, they have cut out of their life to make way for work. They have not realised that the mind does not rest; it is refreshed only by variety. Simple physiological advice, even with reference to Kinsey, may be valuable. It is surprising how many young men in this enlightened age have not realised that masturbation, or even simple nocturnal emission, is an ordinary event, and not a hideous perversion. Sometimes a little straight advice about a love affair that has gone on too long works wonders. Sometimes financial problems have to be discussed so that a bursary can be arranged. Sometimes loneliness or homesickness can be countered by getting an all too scarce place in a university hostel. All these things, many of them in essence hardly medical at all, have a prominent place in the treatment of student distress, particularly in the treatment of the milder adjustment problems.

Support, by which I mean simply keeping in touch, seeing the patient again in a week or a fortnight, is also an essential part of treatment. It may not always be necessary to fix appointments in advance, but it is essential to impress upon the student that he has immediate and easy access to you and that you are pleased to see him and not bothered by him. Not to have to carry one's problem quite alone lightens it a lot, and many a student will be helped by being able to see one repeatedly, even, as it were, only to gossip.

There is no doubt in my mind that a fair proportion of students with severe adjustment problems cannot be helped without formal *psychotherapy*. Any university doctor is bound either to undertake some such treatment himself, or to refer cases for treatment elsewhere. Only a minority of distressed students need psychotherapy, but for them it is irreplaceable.

For a student to begin a course of psychotherapy, particularly a course of psycho-analysis, brings its own problems. Not only is it time-consuming, but it takes a great deal of mental energy. Its immediate aim is not to establish a day-to-day working compromise, but to bring to the surface difficult emotional problems, forcing them into prominence so that they can be grasped and dealt with, however painfully. Often the student, held into the tramlines of an academic course requiring regular and repeated effort, finds it difficult to manage the two things at once. In general the simpler procedures of medication, advice, and support, all that is sometimes called "counselling," are the most appropriate to treating distress among students. Supportive therapy, which cannot be continued indefinitely, has been criticised as a transient and palliative procedure whose benefits will fade once the patient is discharged. But the circumstances and difficulties of the student are themselves transient, and in this work supportive therapy has a place of election.

CAUSES OF DISTRESS

Most of us, having in mind some vague image of summer punting on the backs, think of a university as inherently pleasant. When we realise that many young people are far from happy there, we instinctively feel that there must be something, or some combination of things, superimposed to prevent its natural joy.

Many factors have been invoked as such malign influences. The syllabus is overloaded. Games and recreational facilities are inadequate. There is a dreadful lack of hostels and halls of residence. Social contact between students and dons is less than it used to be. Interest in religion is waning. The grants system sometimes brings up students unsuited for the university as it is, particularly when there are great discrepancies between the cultural backgrounds of home and college. All these things are important and all take their toll. But there is more to it than that. Difficulties, of one sort and another, are the common stock of life, but they do not usually make such havoc of happiness and achievement. More and more I come to feel that for many people there must be some element of severe emotional strain implicit in the process of higher education itself.

But why should university life be difficult? I should say that learning—taking in—absorbing—is essentially a faculty of the young, of the prepubertal. On reaching physical maturity, an animal—or man in the more natural state—becomes independent, fends for himself, takes a mate, produces offspring, initiates rather than copies, acts rather than learns. His *modus operandi* becomes out-going rather than in-taking. In society, however, we block the simple course of Nature. The physically mature is still socially immature. By enjoining a further long period of education, we impose a period of psychological childhood on the physiological adult. For however courteous and sophisticated a university may be, being an undergraduate involves, in essence, a childhood situation. It means a greater or less period of celibacy; a greater or less period of dependence, either on the parents or on a benign parental government; and essentially a period of intensive learning—of in-taking rather than out-putting. It is this discordance, inevitable in a modern society, which I suggest is the implicit difficulty of the student. Many can cope with it and come through their university career with happiness and vigour. Many, even sturdy people, patently cannot.

It may be, then, that the present casualty-list, great as it seems, is nearly as low as we can get it under the present conditions. Any radical improvement might involve really radical changes in the form of higher education. Good universities are soaked in tradition, as good Stiltons are soaked in port; they might find it hard.

Even assuming a preparedness for radical change, it is hard to know what could be done. The fact is nobody now knows where, how, or why the student comes unstuck. The university after all is a productive machine. Time and again we have scrutinised the raw material. Volumes have been written on student selection and thousands of pounds have been spent on selection research. Time and again we have scrutinised the finished product. Industry, the Civil Service, and the Armed Forces—all have advised us about the material they want, and what they in fact receive. Now we are beginning to scrutinise the rejects, the mental breakdowns, and the failures. I fancy the next step should be to scrutinise the machine. It is not sacrosanct, it was made by man, not sent by God. A very small part of the cost of the failures would support a full-scale study of the university, its students, and their mutual impact. Then, but surely only then, we could all make some really sensible suggestions.

DOUBLY HANDICAPPED CHILDREN

RAYNERS SCHOOL, PENN

ANY deaf child, if he is to learn to communicate with his world, needs his wits about him. But when his wits, like his hearing, are defective, then he is handicapped indeed: in a losing race, he falls steadily farther and farther behind his age-group. Yet his mental defect may not be great: he may well be merely feeble-minded; or a high-grade imbecile, able to respond well to appropriate education. Rayners School, at Penn, in Buckinghamshire, caters for just such children, as well as for others who are deaf and mentally normal but handicapped in other ways.

FULL HOUSE

This boarding-school, now belonging to the London County Council, was first opened by the London School Board in 1900, in Hackney; and for many years it was unique in providing education, training, and care of deaf or partially deaf children with additional handicaps. The school was moved from London to the comfortable Victorian house, "Rayners," in 1921. Here it is set in beautiful surroundings, in an old and famous village, with twenty-three acres of gardens and playing-fields about it. With 62 children in residence it is full—even too full. The big, pleasantly coloured bedrooms which have become dormitories contain rather too many beds, the dining-tables are rather too crowded, the classrooms have had to be subdivided, the rooms are not quite light enough, and there is no school hall. The reason for this elbow-jostling is that Rayners—which takes children not only from London (though these have preference) but from all parts of the country—has a waiting-list longer than its roll-call. And so far there have never been any serious epidemics. All the same the work of the school would probably benefit, and the roll could certainly be increased if two or three modern classrooms rose up on the foundations of the old stables, lying near the house.

WORD AND SIGN

Meanwhile, it is a lively and cheerful place, and doing remarkably good work.

Of the 62 boys and girls between the ages of 5 and 16 now in residence, 34 are deaf and educationally subnormal, 17 are partially deaf and educationally subnormal, 2 are deaf and partially sighted, 2 are partially deaf and partially sighted; and 7 have three handicaps apiece, 3 being deaf, educationally subnormal, and physically handicapped, 3 deaf, educationally subnormal, and partially sighted, and 1 partially deaf, educationally subnormal, and physically handicapped.

The fact that some have residual hearing raises an educational problem, as Mr. John H. Blount, the headmaster, has explained elsewhere.¹ For those who can hear a little, the oral system of training—speech and lip-reading—is the method of choice; but when a child is both deaf and dull the great need is to get into touch with him—to establish some precise means of communication—so that his understimulated mind has a chance to respond and develop. In teaching such children Mr. Blount has no hesitation in using finger-spelling. The difficulty comes, as he says, from having children of both types working side by side. It would be better to have them in separate schools; but he does the best he can by keeping them as far as possible in different classes. All the partially deaf children have hearing-aids, and every effort is made to get them to learn to lip-read and to speak. The generous staffing of the school—there are only about 8 children in each class—makes much individual teaching possible. However, when a deaf child finds it impossible to comprehend language (and lip-reading must follow and depend on the comprehension of language), he is taught finger-spelling. A remarkable development in his educability often follows.

It is generally held that once a child has been allowed

to learn finger-spelling he will never take the trouble to learn to speak; and this is probably the case with most mentally normal children. Mr. Blount, however, does not join in the general condemnation of finger-spelling. His own parents, intelligent people, were both deaf, and had both learnt to lip-read and speak; nevertheless, they agreed that in talking to other deaf people finger-spelling was often useful, because it was precise: if they wished to make absolutely sure that a message was understood they used finger-spelling. This is a practical point which deserves reasonable attention.

Mr. Blount would like to be able to segregate not only the deaf from those with partial hearing but also the educationally normal from the educationally subnormal children; for, as he says, if it is thought undesirable to mix these two groups among children who can hear, how much less desirable it is to mix them when the children are handicapped by deafness. He estimates that there are, in England and Wales, about 240 children who need special education as deaf—or partially deaf—with additional handicaps. We need, he thinks, four schools: one, taking about 100 children, for the deaf and educationally subnormal; another for about 60 partially deaf and educationally subnormal children; and two others, each taking about 40—one for mentally normal deaf children with some other handicap, the other for mentally normal partially deaf children with some other handicap. A thorough examination of children in ordinary schools for the deaf would, he believes, bring to light quite 100 educationally subnormal children who had failed to profit by the oral method; and these could be taught far more adequately in a separate school by finger-spelling.

SOME RESULTS

The children in the classrooms at Rayners are certainly alert and responsive, for the most part, especially to finger-spelling. The seniors, even if they do not choose to speak much, are not bad at lip-reading; and the standard of school work (as judged by exercise books) is remarkably high: the best group of children—at present chiefly boys approaching leaving age—can read, write a neat hand, compose a good informative letter, and do quite advanced sums. They are also well-mannered, cheerful, attentive and friendly. In recreation time they play football or cricket on their own playing-fields, help the gardeners, or otherwise enjoy themselves in the grounds and countryside. Those who are normal mentally—and even some who are not—can hope to earn their own living: aftercare records show that 61% find satisfactory employment and become self-supporting, and a further 14%, though not entirely self-supporting, are also in satisfactory employment; 14% prove to be unemployable, and end up in institutions, and 11% have either died or cannot be traced. This seems a record of useful work.

Medicine and the Law

Spinal Anæsthesia

A JUDGMENT¹ in the Court of Appeal has upheld the decision² of Mr. Justice McNair in an action alleging negligence in the administration of spinal anæsthetics. Both plaintiffs had had intrathecal injections of 'Nupercaine' in the same hospital on the same day in 1947, and both had later become paralysed. The judge found that the damage was caused by contamination by the phenol in which the apparently intact ampoules were stored, and he held that the anæsthetist was not negligent in failing to appreciate this risk in 1947. Their Lordships in the Court of Appeal agreed; and Lord Justice Denning added: "We must not condemn as negligence that which is only a misadventure."

Reconstruction

THE AUSTRALIAN HEALTH SERVICE

UNLIKE our own health service, which began on the appointed day "all at once and nothing first," the Australian health service is being introduced in two parts and by easy stages. Long-term plans for capital expenditure on universities, medical schools, and hospitals will form the second part. The first part tackles the prevention and treatment of disease by the provision of free drugs, tuberculosis allowances, and medical and hospital benefits. A basic principle of the scheme is that eligibility for a large part of the benefits depends on voluntary insurance rather than compulsory contributions. The introduction last July of the scheme for medical benefits completed the first part, and offers a convenient opportunity to review the whole scheme.

The first moves were exercises in preventive medicine.

ANTI-TUBERCULOSIS CAMPAIGN

In July, 1950, generous tuberculosis allowances were introduced to ensure that people who were infected would not hesitate to accept treatment. Over 6000 new cases have been discovered since the allowances were introduced. The weekly allowances are:

	£	s.	d.
Patient with dependant wife	9	0	0
Each dependant child	10	0	0
Patient without dependants receiving inpatient treatment free of charge	3	7	6
Patient without dependants not receiving free inpatient treatment	5	10	0

These allowances are subject to a means test which has regard to income but not to property. Thus a patient may have an income of up to £2 (£4 for a married couple) a week without affecting his allowance. Patients who receive these allowances must give up work temporarily and accept treatment and examination in an institution or at home according to medical advice.

The Commonwealth has also entered into an agreement with each State to carry out an anti-tuberculosis campaign. The Commonwealth has agreed to reimburse the States for all approved capital expenditure incurred after July 1, 1948, and all maintenance expenditure above the 1947-48 figure. As part of this national campaign each State has made compulsory the notification of all cases of tuberculosis. Everyone over the age of 14 must have his lungs radiographed. Anyone with tuberculosis and all contacts must accept any medical, X-ray, or bacteriological examination thought necessary. The States have also taken power to restrain recalcitrant patients (such as the tuberculous patient who is a chronic alcoholic) who are a menace to themselves and to the community.

FREE MILK

Another preventive measure introduced in 1950 was the provision of free milk for children. The Commonwealth now provides one-third of a pint of milk free on each school day in the year for 750,000 children under 13. All the States are taking part in this service.

PHARMACEUTICAL BENEFIT

In September, 1950, a limited number of "life-saving and disease-preventing drugs" were made available free of charge to everyone on a doctor's prescription. In the first three years 20 million prescriptions have been made up. At first the list, on which there were no compounds, contained 139 items, and by March, 1951, there were 185 items. The cost of the scheme for the first full year, 1951-52, was about £7½ million. Owing to excessive prescribing of some scarce and expensive drugs, notably the antibiotics, a measure of control has been introduced.¹

1. Dampney, M. J. *Lancet*, 1952, II, 879.

By 1951 a doctor before prescribing streptomycin or chloramphenicol had to obtain a numbered authority from his State director-general of health. The minister of health may declare by regulation that a drug may only be prescribed in the treatment of a disease specified by him.

The list of drugs was prepared by an expert committee which from time to time advises the minister on the inclusion or exclusion of drugs. A research organisation has been set up in the pharmaceutical departments of the Universities of Sydney and Melbourne to test the purity and standard of the drugs supplied.

MEDICAL SERVICE FOR PENSIONERS

Early in 1951 a free family-doctor service, including free drugs, was made available for pensioners and their dependants. This includes everyone who gets an age, invalid, widow's, or Service pension (but not a war pension), or a tuberculosis allowance. The service does not include specialist treatment.

The doctor may make a small charge (not exceeding 5s.) for treatment outside the ordinary hours of his practice. The pensioner and his dependants are entitled, free of charge, not only to approved life-saving and disease-preventing drugs but also to almost all the drugs and preparations in the *British Pharmacopœia* and any combinations of these, but not to proprietary preparations and medicinal or industrial gases.

The scope of medical services and the terms, conditions, and fee schedules of the doctors who provide them have been agreed by the minister of health and the Federal council of the British Medical Association.

HOSPITAL BENEFITS

These were introduced at the beginning of 1951 and are the first section of the scheme to be bound up with voluntary insurance.

There are two forms of hospital benefit. The first, usually called the "ordinary benefit," of 8s. a day, is paid by the Commonwealth to any approved hospital, public or private, in respect of each inpatient, whether or not he is a member of an insurance organisation.

An additional benefit of 4s. a day, called the Commonwealth benefit, is available only to members (or dependants of members) of a registered hospital insurance organisation. It is also available to pensioners.

Most organisations have waiting periods and do not pay benefit for diseases existing when the member joins. But a member, even when he is not eligible for benefit from his own organisation, can claim the Commonwealth benefit.

It is a condition of registration of the hospital insurance organisation that it should be prepared to pay a benefit of at least 6s. a day. A member of a registered organisation can thus count on a hospital benefit of at least 18s. a day (8s. ordinary benefit, 4s. Commonwealth benefit, 6s. private insurance benefit). These benefits are intended to cover only hospital board and nursing care. The cost of medical care is covered by the scheme of medical benefits.

The time of stay in hospital covered for benefit is at least 10 weeks for general treatment, and up to 15 days for maternity care. Doctors may recommend extensions.

MEDICAL BENEFITS

These latest benefits, which began in July of this year, are available only to members (or dependants of members) of an approved medical insurance organisation. But here again members are eligible for a government benefit even when they are not eligible for benefits from their private organisation—e.g., during a waiting period before qualifying for benefit and for chronic or pre-existing illness.

The medical benefit, which is paid directly to the insurance organisation, takes the form of a subsidy towards the cost of treatment. The government's aim is that their subsidy, plus the payment from the patient's own insurance organisation, should "cover the major portion of the doctor's bill."

The government subsidy varies according to the nature of the service. It remains the same whatever fee the doctor charges and whether the service is rendered by general practitioner or consultant. The government have compiled a table of their subsidies which has been divided into two schedules. The first (or minimum) schedule covers consultations and visits and the common medical, surgical, and obstetrical service; the second (or optional) schedule covers specialised services such as radiological, laboratory, and the less common medical and surgical services. An insurance organisation will not be approved by the government unless it provides benefits, at least equal to the government's subsidy, for all the services included in the minimum schedule. The following are examples of the subsidies offered:

Type of service	Commonwealth benefit		Commonwealth plus minimum private benefit	
	£	s. d.	£	s. d.
Professional attendance, non-specialist (at rooms, surgery, or hospital) ..	6	0	12	0
Specialist attendance:				
(a) Referred by another doctor—first attendance ..	1	0 0	2	0 0
(b) Referred by another doctor—subsequent attendance ..	10	0	1	0 0
(c) Not referred by another doctor ..	6	0	12	0
Appendicectomy ..	5	12 6	11	5 0
Exploratory laparotomy ..	5	12 6	11	5 0
Cholecystectomy ..	11	5 0	22	10 0
Antenatal care—seven or less attendances (each) ..	6	0	12	0
More than seven attendances ..	2	2 0	4	4 0
Confinement and postnatal care ..	2	5 0	4	10 0
Antenatal, confinement, postnatal ..	3	15 0	7	10 0

An insurance organisation need not pay benefits for the services in the optional schedule, but its members are still entitled to claim the government subsidy. The government hope that with the backing of the new scheme the insurance organisations will extend their benefits, and members their insurance, to cover the optional schedule. The combined government and private benefits should, they believe, then "largely meet the cost of specialist services."

The government believe that most people who are barred by age and illness from joining a voluntary insurance society will probably be receiving an age, invalid, or widow's pension which will entitle them to free general-practitioner treatment under the pensioner medical service scheme. The Commonwealth subsidy will also be paid to indigent people who are not pensioners.

PROFESSIONAL REPRESENTATION

In his address to the World Medical Association last September, Sir Earle Page, F.R.C.S., F.R.A.C.S., who as minister of health for Australia is chief architect of the scheme, affirmed his belief that its most important feature was that the professions took their place as active partners, and helped to control and implement it through committees chosen from their own ranks. Disciplinary and advisory committees for medicine, pharmacy, and insurance have accordingly been set up.

In Australia, on financial and political matters the whole medical profession speaks through the Federal council of the B.M.A. The Royal Australasian Colleges of Physicians and Surgeons, whose fellows are all members of the Australian division of the B.M.A., have delegated discussions on these topics to the council. From this body the Federal government have been able to get a "representative opinion on all vital matters in a reasonable time."

Other professional committees include the advisory committee which determines which drugs should be on

the free list. It consists of four doctors appointed by the minister from a panel of six nominated by the Federal council of the B.M.A., a pharmaceutical chemist, and a pharmacologist, together with the director-general of the Commonwealth department of health, who is by law a doctor, or his nominee, and a secretary, who is a pharmacist belonging to the department of health. The committee recommends to the minister from time to time the drugs and medicinal preparations to be made available as pharmaceutical benefits, and advises on other matters referred to it by the minister. In the future, drugs or medicinal preparations additional to those already in use may not be prescribed except in accordance with the recommendation made by the committee to the minister.

Medical and pharmaceutical committees of inquiry have also been set up, on a Federal and State basis, to deal with professional misconduct in the pensioner and pharmaceutical services. All the members of the medical committee of inquiry are doctors—the Federal committee consisting of the director-general of the Commonwealth department of health and four members. The State committees consist of the deputy-director of health and four doctors nominated by the organised profession. Appeal to a supreme court against the report of the committee and the decision of the minister is allowed. In cases of obvious fraud and dishonesty, the government may act independently of the committees directly through their own legal department, though even these cases are usually submitted to the committee for report before action.

Public Health

Scotland in 1953

In a preliminary return for 1953 the Registrar-General for Scotland¹ reports that the birth-rate has risen for the first time since the late war. The rate for 1953 was 17.8 per 1000 population, which is 0.1 more than in 1952 but 0.4 below the average for the preceding five years. The death-rate fell by 0.5 to 11.5 per 1000 population. Deaths from all forms of tuberculosis numbered 0.26 per 1000 population, compared with 0.32 in 1952. The infant-mortality rate decreased from 35 to 31 per 1000 live births (the lowest figure yet recorded), and the stillbirth-rate from 26 to 25 per 1000 total births.

Infection from Telephones

Transfer of infection by telephone instruments has often been suspected, but no very serious instances of this have been disclosed by various bacteriological surveys. Williams² has found that the risk is apparently very slight.

Bacterial flora were counted in 153 examinations of telephones in central London street kiosks, in a large City office where no "disinfection" routine was followed, and in another office where weekly disinfection was practised. Swabs moistened in saline were inoculated on to blood-agar and into nutrient broth. *Staphylococcus aureus* was cultured from 7.2% of mouthpieces and 17.6% of earpieces; and one pneumococcus was found. Otherwise no pathogenic bacteria were isolated.

Laboratory experiments showed that *Staph. aureus* and *Streptococcus pyogenes* could survive for several days on the instrument, but suspended particles artificially inoculated on to it were not dislodged by an air current considerably stronger than that emitted in normal conversation. It therefore seems improbable that organisms in saliva or sputum can be dislodged by talking into the mouthpiece, or that there is any appreciable risk of its transmitting respiratory infection.

In England Now

A Running Commentary by Peripatetic Correspondents

THEY had applied for an indoor invalid chair and, to ensure that the need was genuine, they had been asked to attend my outpatient clinic. The patient was the husband, who told me how muscular dystrophy had begun in his right arm when he was 18. Now he was 49 and both arms, both legs, and his back were affected. Until lately, he had been able to walk a few steps, enough to allow him to get from room to room, but this was no longer possible. His wife, a plain little body with thick-lensed glasses, explained "Now I have to carry him about the flat, Doctor, and it is rather too much for me. That's why we want the indoor chair."

Undressing looked like being a tedious job requiring the help of two nurses. But the wife, bustling round like a hen with one chick, had the job finished in less than five minutes. Naked he was a pathetic sight—the great proximal muscle-masses melted away, thighs and upper arms like match-sticks, the grotesque hypertrophy of the calves unable to conceal the gross weakness of his foot-movements. Apart from his face, the only movements left to him were pronation and supination, a fair grip in both hands, and the ability to maintain, but not assume, a sitting posture. But here was no self-pity. As we talked, I learned that he managed to feed himself by having his arms placed on the table when, by supporting one elbow with one hand, he was able to convey food to his mouth with the other. He had traced the other members of his family who were affected and offered to lend me the genealogical tree. He willingly agreed to appear at a clinical meeting. At this stage something dawned on me.

"If this affliction began when you were eighteen, did you ever do any work?"

"I worked until I was twenty-one."

"When did you get married then?"

"Only a few years ago. You see my father and mother looked after me till then, but they weren't able to do so any longer. Then this lady, who was a good friend of ours, said I wasn't going to be sent away, and we got married, so she could look after me."

With a sense of unworthiness, I filled in the appropriate form. Another wheel-chair may ease their burden a little; but nothing can adequately reward this unknown heroine.

* * *

Beauty seems to be spreading. I am a peripatetic physician and journeys from one hospital to another can be varied. In the spring I always pick my way through a village which has the nicest green I know. Last month it was a mass of crocuses—purple, white, and yellow. What a poor description yellow is for that brilliant sheen in the sunshine. This month there are daffodils under the chestnut and elms. But, as so often, beauty is not effortless. I have discovered that many of the villagers subscribe half a crown a year to the upkeep of their green. Every year a few more flowers are scattered here and there in what was once unkempt grass. What is even better, other villages have imitated their neighbours. Lawns are now stocked with bulbs which will soon have their leaves braided so that the mower can do its work.

* * *

During a cocktail party the administrator of our hospital for mental defectives told me that if I needed any help in the garden of my new house he would gladly send me down a few of his "higher grades" to give me a hand.

The garden is a meadow-field stretching in gentle undulations to the still, mirrored waters of the canal. My intention is to convert it into a fine, smooth, shaven lawn on the style of the great chateau gardens which grace the banks of the Loire—or even those flawless, velvet lawns which hem the higher reaches of the Thames. I visualise a lawn so perfect that the sparrows would glance at their feet before alighting on it. With these ideas in my mind I grasped the administrator's offer and asked him to send me four of his best boys on the morrow.

When they arrived I selected one who looked as though he had a less elusive hold on his faculties than his colleagues. I appointed him foreman and he seemed well

satisfied with his early promotion. He said I would not regret my decision. He said he had always wanted to be a foreman and that he was a liberal and believed in free enterprise. This last remark was obscure, but I did not feel it necessary to follow it up.

I told him to get his men to take six inches of the top soil away from a restricted area next the house and then to level the ground with ashes. After watching them take away a few sods to make sure they had understood my simple instructions I went to work.

When I came home for lunch I was amazed to see only one figure in the field. This was my foreman. The other three were lost in an enormous hole and spadefuls of red clay were being ejected high into the sky like the debris from some nuclear explosion. The scene was apocalyptic. The foreman was shouting frenzied orders from the brink of the crater. Ever and anon he fired a fistful of clay at a flagging colleague. This was greeted from the belly of the earth with gales of ungovernable laughter. The hole was so near the house I feared for its foundations and rushed to the garage for a hose-pipe. It was clear the men had gone berserk and a sudden drenching might, I hoped, bring them back to a sense of their responsibilities.

I was assembling the pipe as fast as I could when my wife joined me and explained that she had striven valiantly to hold up the excavations, and, when she had failed in this, to deflect them away from the house and towards the canal. But the foreman was inflexible and told her I had given him instructions to dig a six-foot hole for an ash-pit, and that he had been a foreman far too long to take advice from a woman.

* * *

At our staff meeting last week a consultant complained bitterly that much of his work could be done at registrar level. His remark is not unjustified; but raises the fresh difficulty of defining the upper limits of the houseman's lowliness and the lower limits of the consultant's elevation.

For instance, the level of the surgical registrar, with his tail-end operating-lists for hæmorrhoids and hernia, lies on a distinctly inguino-perineal plane, while that of his orthopaedic colleague is governed by centrifugal force, for his endeavours are confined almost exclusively to the big toe or the little finger. In the E.N.T. terrain the pillars of the fauces form convenient landmarks, golden gates beyond which a registrar rarely trespasses. In gynaecology and anaesthetics the level is not so much a matter of height as of depth, varying in direct proportion to seniority in gynaecology, and inverse proportion in anaesthetics. Classification of the psychiatric registrar is not feasible, for one can never be certain whether his level lies above or below the id.

What about the medical registrar? Why, I see all the patients over ninety.

* * *

When Uncle Arthur, home from the East, feels an attack of malaria coming on, he retires to his room with large quantities of whisky and hot milk. This prophylactic, he finds, never fails to abort the attack. Uncle Arthur has found it necessary to take these precautionary measures more often of late and it has strained his resources, both financial and diplomatic, to maintain an adequate supply of whisky. He might be expected therefore to welcome Professor Maegraith's discovery that a milk diet is protective against malaria and that, instead of being a mere innocuous vehicle for conveying the rare and expensive active principle, the milk itself is the specific agent in Uncle Arthur's prophylactic mixture. But Uncle Arthur is not convinced. He agrees, however, that there is a strong case for a properly controlled clinical trial and he is willing, in fact anxious, to participate. With a rare public spirit he is prepared to volunteer as one of the controls receiving the prophylactic mixture from which the milk has been omitted.

* * *

We were delighted to read¹ that the opossum, *Didelphis virginiana*, has at last come into its own and is to be used in psychiatric research. We can just imagine our psycho-analytical friend conning his appointments for the day: 9 A.M., the manic; 10 A.M., the anxiety; 11 A.M., the depressive; 12 noon, the opossum. Do you think he will hang upside down from the branch of a tree during his analysis?

Letters to the Editor

TREATMENT OF HYPERTHYROIDISM

SIR.—I should like to express my appreciation of your excellent leading article last week.

There is one point, however, which is open to criticism—namely, the care of the hyperthyroid patient after operation. You imply that thyroidectomy is very similar to appendicectomy, an incident in the patient's lifetime, and that after a fortnight in hospital and a fortnight's convalescence, she returns to work cured. This is not true of the great majority of cases. The postoperative thyroid convalescence consists in two stages: the primary stage starts immediately after operation, goes on for a few weeks, and brings a great improvement in the patient's health; but very often residual symptoms, especially fatigue and nervous phenomena, linger. The complete recovery may be long delayed, and the secondary advance may occur after nine, twelve, or fifteen months. The patient may, especially if she is debilitated and the disease is of long standing, improve more during the second year than during the first. It is possible for a careful clinical observer to foresee in which cases complete recovery will be slow, and such patients are very grateful if they are told beforehand that this slow progress is no reason for despondency.

If a patient is not progressing satisfactorily three or four months after operation, the following questions should be considered. Firstly, was the original diagnosis correct? Secondly, was the amount of thyroid tissue left at operation (estimated and recorded in the notes of the operation) what the surgeon judged to be the optimum amount? Thirdly, is there any concomitant condition hindering recovery? Fourthly, is there any adverse influence in the patient's life? The last question is most important. If, for example, a woman is living alone with a sister and constantly quarrelling, or if she is harassed by a dominating and interfering mother-in-law, or if she dreads return to work because she fears an overseer who has got a hold over her, it is most unlikely (however perfect the operation) that she will recover from her nervous phenomena until the exciting cause has been removed. If all these questions can be satisfactorily answered, the patient can be told with confidence that complete recovery will occur in due time.

Treatment with thiouracil is considered to act in the same way as thyroidectomy, only more slowly. This is not quite correct, for a patient who remains uncured under full treatment with thiouracil may quickly and dramatically respond to operation. Nevertheless, the parallel is close enough to suggest that these factors, which are borne in mind by the careful surgeon during the convalescence of his hyperthyroid patients, should also be kept in mind by the physician using one or other of the modern methods of medical treatment.

Bradford.

PETER MCEWAN.

KWASHIORKOR

SIR.—We agree with Professor Moncrieff¹ that discussions of the etymology of "kwashiorkor" are making heavy weather. If his suggestion were accepted that the word means "the deprived child" it would simplify the issue and fit in excellently with the concept of "protein malnutrition" in weanlings which has now been clearly defined.² It would also meet the criticism of Dr. Kahn³ that the concept of redness attached to the word is preventing people from diagnosing the

syndrome when the characteristic pigmentation of skin or hair is lacking.

In defence of the position which we took in our monograph,⁴ we must point out that we were concerned solely with the syndrome as seen in Africa, and we were urging what we thought to be a correct etymological use of the word kwashiorkor. We are dealing with the etymology of the word in another place, but there is no doubt that when the monograph was written the accepted meaning of "kwashiorkor" was "red boy," and there seems no doubt that the native names *mbuaki* and *diboba* do refer to the special pigmentation of hair and skin. The word kwashiorkor is derived from the Ga language of the Gold Coast, and scholars of this language assure us now that it did not refer to pigmentation but apparently to the psychological state which arises when the child is deposed from the breast at the time of a second pregnancy or birth. We therefore like Professor Moncrieff's suggestion that it should be regarded as meaning "the deprived child"; this would obviate further mental gymnastics on this subject, and would fit in well with the decision of the F.A.O./W.H.O. Committee to apply the name to similar or related syndromes throughout the world.⁵ A decision to abandon the concept of redness would apparently have the support of Dr. Cicely Williams⁶ who introduced the word into European medical literature.

Turning to more practical considerations, we suggest that the term kwashiorkor should be used, at least in Africa, to denote protein malnutrition (subacute as well as acute), occurring during the late breast-feeding, weaning, and postweaning phase of life in regions or under conditions in which starchy paps are used as supplementary or postweaning feeds to the virtual exclusion of protein-rich foods (such as cow's milk, goat's milk, and mushes prepared from legumes, nuts, or fish). Since in Africa and many other underprivileged parts of the world the child is retained at the mother's breast until displaced by the next succeeding child, the syndrome comes to be one of the "displaced" or "deprived" child. In our monograph we confined our description to young children, although we recognised that a similar if not identical syndrome was seen at all ages in childhood, and even occasionally in adults. The new interpretations of the etymology of the word would apparently preclude its use in older children and in adults, but we leave this question open.

It is not yet clear how many of the considerable variety of physical signs and laboratory abnormalities must be present before it is legitimate to use the term kwashiorkor. The answer to this must await further knowledge of the pathogenesis of the disease. We agree that dyspigmentation of the skin and hair is not essential to the diagnosis, and that *mehlnährschaden* differed from kwashiorkor as we saw it in Africa only in the absence of the dyspigmentation of the skin and hair which is so often a striking feature of the African cases.

Dermatosis is certainly not necessary for the diagnosis, and the term infantile pellagra is misleading when applied to this syndrome. Pellagrous or pellagroid dermatosis occurs particularly in those children fed on a starchy pap prepared from maize (corn). Other types of dermatosis or no dermatosis at all may be found in those consuming other types of starchy pap. Some at least of the dermatoses are due to associated vitamin deficiency.

We agree with Dr. Kahn that this form of malnutrition may be primary or secondary, and that the syndrome may take a variety of clinical forms, but we do not

think it necessary to coin such terms as "malnutrition with fatty liver" and "malnutrition with kwashiorkor." The problem of terminology is simplified if it is accepted that the term kwashiorkor may be used to denote a spectrum of clinical states of "protein malnutrition" as defined by the F.A.O./W.H.O. Committee.² Each protein food differs in its amino-acid composition and is also the vehicle for other nutrients in varying combinations, the deficiency of which might, apart from amino-acids, play a part in the production of different features seen in this syndrome.

As long as the precise aetiology of the syndrome is no better defined, the name "kwashiorkor" seems to us, at least when applied to weanlings, to be as good as, or better than, any of the others in the list given in an appendix to the report.²

HOSPITAL BEDS FOR CHILDREN

SIR,—The estimate made by Sir James Spence and Dr. Mary Taylor (April 3) that 50 beds for children are needed for each 100,000 of population raises interesting issues in relation to the provision of children's beds in London. Comparable figures for London in 1950 are not readily available, but the following statistics of population and hospital discharges or deaths in the Administrative County of London for 1952 seem a reasonable basis for comparison:

	Newcastle 1950	London County 1952
Total population	294,800	3,343,000
No. of children under 15 years of age ..	66,130	656,000
Children as % of total population ..	22.4	19.6
No. of children under 15 admitted or discharged	4240	65,201
Children admitted or discharged as % of all children	6.4	9.9

The number of children discharged from London hospitals in 1952 is taken from the SH 3 returns submitted to the Ministry for that year. If anything, it is an underestimate, since only children discharged from children's hospitals or children's wards of adult hospitals are included; children discharged from tuberculosis, infectious-diseases, and mental institutions are excluded, and some hospitals did not differentiate between adult and child discharges in their returns. The proportion of children treated in hospital in London is higher than in Newcastle. Why this should be so is hard to explain, but one reason may be that many children from the Outer Ring of Greater London and elsewhere are treated in the hospitals in London County. Again, since seven of the ten general children's hospitals in the county are teaching hospitals, more beds are needed in them to meet both teaching and regional needs, and the same applies to the children's departments of the other teaching hospitals in London.

According to Spence and Taylor's estimate, at least 1675 children's beds are needed in the County of London. Exact figures of the actual number provided are not readily available, but according to the SH 3 returns for 1952, 25,070 children were discharged from the ten general children's hospitals, with a total bed complement of just over 1000 beds, and 40,131 children were discharged from the children's wards of other hospitals in the rest of the county; if the number of discharges bears any relation to the number of beds, these figures suggest that there are possibly over 2600 children's beds in London County. This figure can only be a rough approximation, since the method of calculation is not fully reliable, but it lends some strength to the argument that there may be more beds for children in

London than are really needed. The occupancy-rate (averaging 83% of the beds available in 1952) and the waiting-lists (over 4300 for E.N.T. admissions and over 1700 for other reasons) of the children's hospitals do not wholly support this argument, but it would be dangerous to draw dogmatic conclusions without information about children's wards in adult hospitals and about many other variable factors.

There seems to be a case for an investigation of this kind, leading to a consideration of general policy. If either now or in the future there should prove to be more children's beds than are needed in London County, or in Greater London, should the children's hospitals be developed as centres of paediatric treatment and education, and beds reduced elsewhere? Or should the children's departments in adult hospitals be retained and the children's hospitals be reduced in number or size? Or should children's hospitals and children's departments in adult hospitals alike be gradually whittled down by each governing body as it thinks fair?

At present these questions, and the dependent issues of medical staffing and the training of nurses, are dealt with by a variety of bodies. Patients in London County are drawn from the areas of four regional hospital boards; the ten general children's hospitals are controlled by six different boards of governors and two hospital management committees, and the children's departments of adult hospitals are controlled by over twenty-five other boards and management committees. Local-health authorities are also concerned. With so many interested authorities there is a danger that the problem, which is in many ways a regional one for London County and Greater London as a whole, may not be viewed as a whole. It perhaps merits more concentrated and coördinated attention than it has hitherto received.

London, S.W.5.

M. C. HARDIE.

THE FACE IN DIAGNOSIS

SIR,—I have read and re-read the interesting article by Pierrhos StKatsareas.¹ I should like to add to his long list a few more conditions in which the face carries stigmata of disease.

(a) In pellagra, the face, neck, and a V-shaped portion of the front of the chest show characteristic dermatitis. On the face this is often symmetrical and butterfly-shaped.

(b) In Egypt, it is common to see patients who have a pale face and chronic enlargement of the parotid glands—so-called endemic parotitis—a condition often found in patients with ankylostoma anaemia, although the connection between the two conditions is not clear.

(c) The face of the patient with liver abscess has a typical earthy colour.

(d) The patient with advanced carcinoma of the urinary bladder, cystitis, and ascending pyelonephritis has a typical appearance, though this is difficult to describe.

(e) The child with cervical Pott's disease is easily recognised because he is continually supporting his chin with his hand.

(f) In gargoylism the face and the skull show characteristic features. The face has a peculiarly unchild-like look reminiscent of Tenniel's illustrations of the Duchess in "Alice in Wonderland." Whereas the hair is often fair and silky, the eyebrows are almost invariably dark and coarse. The eyelids, nose, and lips are grossly thickened. Deep creases run from the nose to the angles of the mouth. The bridge of the nose is depressed. In some cases, there is a moderate degree of hypertelorism. Distension of the skull veins has been described, the frontal veins lying in deep gutters. A characteristic feature is clouding of the cornea by multiple opacities. The skull varies considerably in size and shape, and is commonly enlarged. It has been described in different instances as hydrocephalic, scaphocephalic, and acrocephalic.

1. StKatsareas, P. *Lancet*, 1953, ii, 929.

StKatsareas's article included mumps, facial erysipelas, and labial chancre, so this may justify the mention of some other conditions in which the face is involved:

Rodent ulcer; epithelioma; leishmaniasis; lupus; dermoid cyst; sebaceous cyst; sebaceous adenoma; sebaceous adenocarcinoma; the various swellings connected with the parotid gland, including Mikulicz's syndrome and uveo-parotitis; reticulosis (including Boeck's sarcoid); the various swellings of the upper and lower jaws; pachydermatocele and the café-au-lait patches of von Recklinghausen's neuro-fibromatosis; secondaries in the face, scalp, and skull from a malignant primary elsewhere; the various angiomas, cirroid and arteriovenous aneurysms; prognathism and congenital recession of the mandible; and proptosis, unilateral or bilateral, pulsating or non-pulsating.

The face may also bear stigmata of past trauma, surgical or otherwise:

Burns and Horner's syndrome (mentioned by St. Katsareas) auriculotemporal syndrome (mentioned by Dr. Parkes Weber²); drooping of the angle of the mouth following damage to the cervical branch of the facial nerve after operations high up in the neck; complete or partial paralysis of the facial nerve after operations on the parotid gland; deformity of the jaw after dislocation of the temporomandibular joint or operations on the joint or the mandible; and deformity due to depressed fracture of the zygomatic arch, fractured maxilla or mandible.

THE CURABILITY OF CANCER

SIR,—I have read with great interest your leading article of April 3, which includes references to cancer education and early diagnosis. The value or otherwise of such education, even in the case of the breast, has not been proved, and still less for the other accessible cancers. Surely this part of the problem is of sufficient importance to justify further intensive research, which should be carried out "step by step," as indeed is being done on a small scale by the Yorkshire Council of the British Empire Cancer Campaign. Another experiment, I understand, is being carried out under the auspices of the Manchester Radiotherapy Centre, but there is room for much more investigation.

There are 5 fundamental questions to which answers are needed, in the following order:

- (1) Will intensive education cut down the delay in reporting certain symptoms (about seven in number), whatever the cause may be, but which may suggest the presence of an accessible cancer in the breast, uterus, rectum, tongue and mouth, larynx, lip, and skin? Probably this is the only question likely to be answered by the small Yorkshire experiment.
- (2) If the delay is cut down, will it result in an appreciably greater number of clinically early-stage accessible cancers being treated in hospital?
- (3) If a greater number of early-stage accessible cancers are treated at hospital, will the "five-year cure-rate" of these accessible cancers be increased?
- (4) If the "five-year cure-rate" is increased, will it result in a lower mortality from these accessible cancers?
- (5) Will cancer education increase the apprehension, which at present exists in almost 100% of the population, or increase real fear, which happily exists in only a small proportion of the public? If it was proved that apprehension and fear were increased, this would be a very serious objection to public education, even if this could save a few thousand lives.

It would seem that Professor McKinnon believes the answers to (1) and (2) in cancer of the breast are in the affirmative, although exact critical figures published are few; and that the answer to (3) may be in the affirmative owing to the inclusion of a large number of non-metastasising, "non-lethal cancers." He seems convinced

that the answer to (4) is in the negative. The 5th question is very difficult to answer. In my opinion, after giving about 120 lectures within the last year to several thousand lay people, the psychological effect of such education is good; and the votes taken at the end of some of those lectures are overwhelmingly in favour—3348 in favour and 10 against. One thing is quite certain: if cancer education increases fear and apprehension, it will defeat its own purpose—namely, to get early diagnosis.

Everybody will agree that the most important factor governing the mortality from cancer is the type of tumour; but the question still remains, Are there a sufficient number of late metastasising but still "lethal" cancers to justify every effort to get the earliest possible diagnosis and treatment? Only a large-scale experiment on the lines suggested above can prove or disprove this.

Cancer Campaign, York.

MALCOLM DONALDSON
Director of Cancer Survey.

BENZATHINE PENICILLIN IN YAWS

SIR,—Much attention has lately been given in the British medical press to the side-effects of antibiotics. Although penicillin has been used for a longer period than other antibiotics, its side-effects have only recently been appraised more thoroughly. Efforts have been made to develop penicillin-derivatives, such as allyl-mercaptomethyl penicillin, causing fewer sensitivity-reactions, and clinical trials have been undertaken in search of salts of penicillin with repository effect which would obviate the use of procaine or oily components now contained in repository preparations—e.g., procaine penicillin G in water or in oil with aluminium monostearate (P.A.M.). Thus, benzathine penicillin (N'N' dibenzylethylene-diamine dipenicillin G), also known as diamine penicillin, 'Penidural,' 'Bicillin,' 'Tardocillin,' &c., and benethamine penicillin (N'benzylphenylethylene-amine penicillin G), also known as 'Benapen,' have been described for oral and parenteral use in various infections.

The treponemacidal serum-levels obtainable with benzathine penicillin—a penicillinæmia of 2-3 weeks' duration follows a single injection—has made it an even more promising drug than P.A.M. in the treatment of syphilis. Recently this salt has also been tried in the yaws programme of the Thailand health administration. Among 236 yaws patients, some with early infectious yaws and others with palmar and plantar hyperkeratosis, side-effects were recorded in 11.2% of cases: 2.5% of the patients said they had been feverish for 2-5 days after the injection; another 5.6% had fever plus pain at the site of injection; and 3.1% had local pain only. On the other hand, there were no local or general skin-reactions or allergic responses in this series. Admittedly the reactions were assessed from the patient's own stories (no temperature measurements were taken), but their incidence was considerably higher than that reported (1%) with benzathine penicillin (and with P.A.M.) in the treatment of early syphilis in American patients. On the other hand, it is remarkable that the types of local and general skin-reactions and allergic responses which were commonest during the treatment of syphilis in the U.S.A. were not recorded at all among the yaws patients in rural Thailand. This suggests the importance of sensitisation by the widespread use (and misuse) of penicillin in industrial areas where the antibiotic is freely available, as contrasted with areas where the population has had no penicillin. There is also the possibility of a different underlying general tissue-response to stimuli of this kind.

In Thailand, two treatment schedules were used—namely, 0.6 and 1.2 mega-units of benzathine penicillin, given in a single injection. No difference in results between the two schedules was observed in either of the

2. Parkes Weber, F. W. *Ibid.*, p. 995.

two groups of patients. The clinical and serological effects after six months were excellent: complete healing of lesions took place in 98.0% and 89.7% of the early infectious yaws and the hyperkeratosis group respectively. While 14.3% of the patients in the former group became serologically negative, no case of hyperkeratosis showed complete reversal after six months. There was significant improvement in serum titres (quantitative V.D.R.L. tests) in both groups, the average improvement in titre representing 2.83 and 2.34 tubes in the two series. These results were better than those given by 2.4 mega-units of P.A.M. under similar circumstances in the same rural areas of Thailand.

DOSAGE OF MEPHENESIN

SIR.—In his letter of Dec. 19 Dr. Peckover discusses the dosage of mephenesin necessary for the effective treatment of various "rheumatic" complaints encountered in general practice.

I have found that mephenesin, administered in the single doses suggested by Peckover and Nesbitt, gives rise to troublesome side-effects, especially nausea and, less frequently, vertigo. Thus, when I obtained some compound tablets in which mephenesin did not exceed gr. 1 per tablet, I tried them and was impressed by their equal if not superior effectiveness, quite apart from their undoubtedly lower toxicity. By cutting down the single dose and combining it with other drugs, the daily amount of mephenesin could even be stepped up with advantage to a total of gr. 9-12 plus the other effective drugs, such as salicylates. This suggests that compound tablets have a useful effect on the pain and spasm, and that side-effects are rarer. The promising future of mephenesin in antirheumatic therapy may lie in its combination with other drugs rather than in its use alone.

ON CREDULITY

SIR.—As a nurse and a member of a family of doctors, I have been brought up on orthodox views of medical science. Like many people, I have seen the failures of medicine, but I have also seen the brilliant results of team-work. So it was with interest that I read Lord Moran's story (Jan. 23) about his friend's experience of osteopathy.

I recall some years ago saying to a friend that I firmly believed that orthodox medicine could offer all that the unorthodox approach to healing could do, especially in orthopaedic surgery and physical medicine. Little did I know how my faith was to be tried.

Some 18 months later I had an acute attack of sciatica, and the pain was very bad. I was told that the cause was a prolapsed intervertebral disc, and I was treated with rest and drugs. I was able to get about for a while, but the acute pain soon returned. A specialist advised me that manipulation under anaesthesia was needed, but it only made the pain worse.

In the weeks that followed I received various forms of treatment, including spinal traction, a plaster jacket, and further rest in bed, but I was still in acute pain and unable to carry out my duties. Even so, my faith was not shaken: I must be, I told myself, a very resistant case. So when, some 7 months after the pain began, a nursing sister suggested a visit to an osteopath, I was not keen at first, but the pain made me change my mind.

Unlike Lord Moran's friend, I found that my initial consultation included a very thorough history-taking, and a careful physical examination. Treatment was delayed until radiological confirmation was obtained. The osteopath told me that the manipulation under anaesthesia had been a bad mistake, which I quite believe. Treatment was not in any

way forceful, and after the fourth visit the pain had gone from my leg, and with a further four treatments it had disappeared altogether.

I have talked to many of this osteopath's patients, most of them with a similar history to my own, and I have come to the conclusion that a lot of suffering could be eased, if not cured, by immediately seeking the advice of an osteopath.

TUBO-OVARIAN TORSION AND TORSION OF HYDROSALPINX IN CHILDHOOD

SIR.—The following two cases seem worth reporting because, although it is mentioned in some standard textbooks, acute tubo-ovarian torsion in childhood does not appear to be common. The clinical picture resembles that of acute appendicitis, and its true nature is disclosed only by laparotomy. Moreover, although torsion of ovarian cysts in infancy and childhood is not uncommon, I can find no record in the standard works of torsion of hydrosalpinx in a child. Most authorities state that this condition occurs only in adults and as the end-result of long-standing pyosalpinx in which the pus has long been resolved and clear fluid left. In the second case there was no history of long-standing pelvic disease and no evidence at operation of any prior pelvic disease.

CASE 1.—A girl, aged 7, was admitted to hospital on Dec. 6, 1953. Forty-eight hours before admission, she felt sick and vomited several times during the evening and the night, and apparently had generalised colicky pain. Twenty-four hours later, the pain settled in the right side and persisted until admission, keeping her awake at night. Her bowels had not been open since the onset of pain. There was some increased frequency of micturition and dysuria during the twelve hours before admission.

She was a healthy-looking youngster. Her temperature was 100.2°F. There was tenderness and rigidity in the right iliac fossa. Laparotomy was performed on the night of admission. A right transverse gridiron incision was made; there was some free fluid in the peritoneal cavity. The appendix was normal. There was torsion of the right ovary and tube, both of which were gangrenous. The right ovary was filled with blood-clot, and was about 3 in. by 2 in. in size. The right tube was $\frac{3}{8}$ in. in diameter, and gangrenous to within $\frac{3}{4}$ in. of the uterus. Right salpingo-oophorectomy and appendicectomy were performed. Postoperative convalescence was uneventful.

The pathologist reported hæmorrhagic infarction of the ovary and fallopian tube.

CASE 2.—A girl, aged 13, was admitted on Dec. 6, 1952. Three days earlier she had had intermittent pain in her back, and she had vomited once. The pain had recurred in the left loin, and for the past twenty-four hours had been constant in the lower abdomen. During the past twelve hours micturition had been painful. The bowel action had been normal, but there had been some frequency of micturition during the past two days. Her periods had started two months ago.

She looked healthy. Her temperature was 100.8°F. There was some tenderness in the left lower quadrant and the hypogastrum, and in the pouch of Douglas on rectal examination. Laparotomy was performed on the day of admission, using a right transverse gridiron incision. There was blood-stained fluid in the peritoneal cavity and a normal appendix. Torsion of the distal two-thirds of the left fallopian tube had made it purple and gangrenous, and it was distended with blood to a diameter of 2 in. The left ovary was normal. The right ovary contained a small cyst filled with blood. The right tube was normal. Left salpingectomy and appendicectomy were performed.

Postoperative progress was uneventful and the patient was discharged on Dec. 16, 1952. When seen at outpatients on Jan. 8, 1953, she was quite well.

The pathological report described hæmorrhagic infarction, suggesting torsion of a hydrosalpinx.

R. F. READ.

TREATMENT OF VARICOSE ULCERS

SIR,—It appears to me that, in his letter of April 3, Mr. Lee is only adding to the "multitude of treatments" and "maze of medicaments and bandages" to no advantage by the injection of tolazoline and hyaluronidase in the treatment of varicose ulcers.

The ulcer which results from the presence of varicose veins is a common one and is easily cured by the removal of the varicose veins. Injections alone play no part in this treatment, and the correct treatment is a Trendelenburg operation plus ligation of all incompetent communicating veins.

The ulcer arising as a post-thrombotic incident is probably even more common. It is wrong to imagine that arterial spasm plays any part in the onset or the chronicity of these ulcers in the ordinary case. I have performed very many arteriograms on these cases and have never found arterial spasm to be present. The post-thrombotic leg may indeed be an "inverted Guinness bottle," and in these cases a supporting bandage is of no value whatsoever, for there is no oedema of the foot or lower leg. A more common type of post-thrombotic leg is one with chronic hypostatic oedema, and in these cases supporting bandages are invaluable, for it is to prevent the accumulation of oedema that the bandages are required and not to get rid of "accumulated metabolites."

It is again incorrect to state that "ligation of the communicating vein does not have any effect"; in most cases it has a very dramatic effect, but to perform the ligation the ulcer has usually to be excised.

Varicose ulcers and post-thrombotic ulcers may be healed and prevented from recurring in most cases by Biggaard treatment and supportive bandages. A cure can be effected, however, by adequate surgical elimination of incompetent varicose veins in both types of ulcers—plus the ligation of incompetent deep communicators (the "ankle blow-out syndrome"). A chronic ulcer may have a base of fibrous tissue at least an inch thick, and I have excised many like this. Surely the best treatment is to get rid of this thick avascular fibrous tissue, and a graft will then have some chance of remaining alive with a healthy blood-supply.

For the really bad cases, lumbar sympathectomy is invaluable to improve the nutrition of the skin. I can see little reason to support repeated intra-arterial injections with their very temporary effect, nor can I subscribe to the repeated needling for the purpose of injecting hyaluronidase which will only spread the oedema over a wider area—in an area which is very susceptible to infection and ulceration at the best of times. Neither of these two methods appears to me to "attack the underlying condition."

Essex County Hospital,
Colchester.

ROLAND N. JONES.

SIR,—Has not Mr. Lee succeeded only in misting a little further the windscreen of varicose-ulcer treatment? To use his own words, we are bogged down already with "a multitude of treatments" and a "maze of medicaments"; but he has no compunction in thrusting intra-arterial tolazoline injections and hyaluronidase ionisations into our already bulging knapsacks.

To me it has always been a source of mystery why the treatment of gravitational ulcers should be so fraught with difficulty, when all that is necessary is to read *The Lancet* of Feb. 28, 1931—and act accordingly. Particularly in these days when the introduction of 'Poroplast' flexible adhesive bandages has virtually banished the boggy of skin sensitivity. May I hasten to add, however, that poroplast is to my mind a most misleading name: the porosity of the bandage matters not two hoots.

What is important is the new plaster spread, which seemingly contains no irritant substances.

I have, up till now, steadfastly maintained that all gravitational ulcers (except in bedridden patients and those over ninety years of age) can be healed with elastic adhesive bandages—*unless the skin is sensitive, when they must go to bed.* With this latest development in the adhesive spread, I withdraw my *italics*.

BLINDNESS AND OXYGEN

SIR,—In your leading article of Jan. 9 you mention the interesting experimental work by Ashton et al. and Patz et al., who produced evidence incriminating oxygen in the development of retrolental fibroplasia.

We published in 1952 a preliminary report¹ in which we described changes occurring in newborn mice that had been intermittently exposed to an atmosphere of 100% oxygen. These changes consisted of hæmorrhages into the vitreous body and behind the iris, persistence and hyperplasia of the tunica vasculosa lentis, and detachment and folding of the inner layer of the retina. These studies are continuing.

TUBERCULOSIS YARDSTICKS

SIR,—The success of modern advances in the treatment and diagnosis of tuberculosis is reflected in the rapidly falling mortality and the persistently high level of new notifications, but, as Dr. Tattersall points out in his letter of April 3, these rates are of no value in assessing the success or otherwise of our attempts to lessen the frequency of tuberculous infection or even bring about the eradication of the disease.

Dr. Tattersall and his colleagues² have shown us the most useful yardstick for this purpose: it is the incidence of tuberculous infection in the school-child as measured by the tuberculin skin-test. This test in its various forms is being more widely used, as part of the routine school medical examination, to discover children infected with tuberculosis so that their contacts can be examined and the source of the infection traced.

It would therefore be a simple matter for the school medical officer to publish the incidence of infection in the various age-groups and in different schools. From these figures it would be possible to compare the incidence of infection area by area and school by school for the whole country. Efforts to discover the sources of infection could then be concentrated in those areas showing a high incidence of infection, particularly in the younger age-groups. Yearly changes in the incidence would indicate the success or failure of our efforts to control the disease.

Dr. Tattersall suggests a list of "active cases" as another yardstick. All would agree with the value of such a list, particularly if plotted on a street or parish map of the area and related to the incidence of childhood infection and the tuberculous morbidity of the area. An "active case" is difficult to define and must depend largely on the result of bacteriological examination of sputum and laryngeal swabs. Even more difficult will it be to say when a case ceases to be active; must there be one, two, or three negative sputum or laryngeal swab cultures and at what intervals?

1. *Acta pædiat., Stockh.* 1952, 41, 577.

2. MacDougall, I. A., Mikhail, J. R., Tattersall, W. H. *Brit. med. J.* 1953, 1, 64.

An investigation (unpublished as yet), recently made at the Ipswich chest clinic, has shown that child contacts of patients with radiological evidence of tuberculosis but repeatedly negative sputum cultures have a significantly higher rate of infection than do normal school-children in this area. This suggests that we cannot rely upon bacteriology in determining the infectiveness of a particular patient, and it is just these patients that should be included in the "active case" list; but by what criteria?

D. VAN ZWANENBERG.

HOSPITAL, DOCTOR, AND PATIENT

SIR,—Your correspondent, "Parent" (April 3), has indeed been unfortunate in her experience of reticence and silence on the part of the hospital concerned. Any parent or relative can interview me or my assistant merely by asking the ward sister for an appointment (or by writing to request one). Under no circumstances is such an interview refused.

Similar practices apply in most of the hospitals I know.

NEW TANK RESPIRATORS

SIR,—In your annotation of April 3 you suggest that the dome system incorporated in the Bristol respirator, described in the same issue, is of such a complex design that construction is a difficult matter.

In actual fact the design of the dome system is very simple and uses the pump unit on its positive stroke, the pressure being regulated by a simple "blow-off" valve. The use of this dome is so easy that it can be learned in a few minutes by an intelligent nurse, and the switch-over from negative pressure in the tank to positive pressure in the dome is so smooth that patients hardly notice it has happened.

In my experience positive pressure maintained through a face-mask is uncomfortable for the patient, who requires education in the use of this method, and it is a difficult technique which cannot be readily left in the hands of nurses.

near Bristol.

JAMES MACRAE.

SPONDYLOSIS

SIR,—I would not venture to criticise Sir Russell Brain's oration, published in your issue of April 3, had it been confined to the clinical aspects of his subject, but some of his statements are on radiological matters and may mislead those who look to him for guidance.

Sir Russell states: "Look back for a moment and recall that it is just twenty years since sciatica was first attributed to an intervertebral disc protrusion." Though the clinicians may not have noticed it, radiologists have been drawing attention to disc lesions for much more than twenty years. He will find evidence of this in my Robert Jones lecture,¹ written in 1926.

Radiologists are well aware that radiographs may show extensive changes of the nature of spondylosis and yet the patient at the time may exhibit few or no clinical signs; and that there may be prominent clinical signs in cases with little or no radiographic evidence. The radiographic signs are the end-result of a series of changes and not the cause, and, as I have shown, there is a long latent negative radiographic period between symptoms and radiographic signs. Why then does Sir Russell

urge multiple views of the spine to show the lesser signs? Surely it is the clinical manifestations which matter.

He says "without the flexed and extended lateral views it may be impossible to detect spondylolisthesis (fig. 4)." Surely an ordinary lateral radiograph would have revealed the lesion shown in fig. 4? I fear that his advice will lead to very considerable waste in time and material to get that which contributes little. And is not this use of the term spondylolisthesis unjustified in such a case? The term was introduced by Killian in 1852 to denote progressive gliding of an unstable vertebra; but fig. 4 gives no indication of this.

Some may find it hard to understand Sir Russell's advice that "it is important to bear in mind the following points in the interpretation of the X-ray appearances . . . the absence of posterior osteophytes, which are radiographically visible, does not necessarily mean the absence of a disc protrusion" (my italics). I rather fear that this may tempt the surgeon to interfere, leaving the patient worse than before.

Sir Russell Brain concludes his article with the statement: "How much we have learnt since then!" I suggest it would be better to ask: "How much have we learnt since then?" My answer would be that apparently nearly everything remains to be discovered, for have we not overlooked the common causes for the acute signs when radiographic changes are absent or minimal? And have we not neglected the preventive measures of disciplined rest and elimination of metabolic and infective toxins which bring degeneration of the discs?

Birmingham.

JAMES F. BRAILSFORD.

SIR,—Thanks to Sir Russell Brain, the neurological symptoms of spondylosis are being more often recognised and better understood. It is less widely known that the protean manifestations of this disease may comprise dysphagia and recurrent laryngeal nerve palsy, which bring the patient to the laryngologist.¹

The patient, middle-aged or elderly, complains of the feeling of a foreign body in the throat, "like a crust,"

which makes him want to swallow. Radiography shows the typical appearances of cervical spondylosis in the posterocoid region, involving C5, C6, and C7 (see figure). The dysphagia is not due to a mechanical obstacle caused by the presence of osteophytes, but to reactive changes in the areolar parapharyngeal and paracæsoophageal tissue, resulting in fixation and impaired mobility of the pharyngeal wall. One or both recurrent laryngeal nerves, which are surrounded by this tissue, may

become involved. Oesophagoscopy must be performed in order to exclude posterocoid carcinoma, but cervical spondylosis undoubtedly accounts for a number of cases which are wrongly dismissed as "hysterical" dysphagia or "idiopathic" recurrent laryngeal palsy.

Parliament

The Budget

ON April 6 Mr. R. A. BUTLER, the Chancellor of the Exchequer, presented what he described as a carry-on budget. He made only minor changes in the existing basis of taxation. For the social services in 1954-55 he has set aside £1327 million, and he pointed out that it takes the whole of the taxes from tobacco, beer, spirits, and purchase-tax to provide this sum. The National Health Service's share has gone up from £411 million for last year to £430 million. Progress in social reform, Mr. Butler believed, had been well maintained. Such progress carried heavy obligations from which there was no miraculous and painless escape. "We cannot," he said, "in good conscience, put the clock back; but we must make sure that in the administration of this vast outlay humanity goes hand in hand with economy."

Health and Welfare

In the House of Lords on April 7, Lord SALTOUN moved

"That in the opinion of this House a large proportion of the failures in the welfare and health services are due to imperfect coördination between the various authorities concerned, that local resolution of difficulties is essential to an efficient service, and that in many cases greater local discretion, financial and administrative, would result in better service at less cost."

He began by reading a list of some of the departments and authorities concerned with the functions of the Welfare State. If all these bodies acted in complete harmony it would be little short of a miracle. But the field of exercise of their functions was the body of one unfortunate man, woman, or child who suffered when these august parties were dilatory or disagreed. Division of responsibility often aggravated shortages of accommodation; and many hospital administrators and welfare workers were convinced that there was an urgent need to have someone with the power of commanding an emergency bed in a hospital and deciding on the spot how any urgent case should be dealt with. Old people, in particular, fell into the gaps between National Assistance, local-authority welfare, national hospital, and local-authority sociomedical services. If the Government could not accept the motion, Lord Saltoun hoped they would appoint a small committee to find how better coördination of these services could be achieved.

Lord BEVERIDGE welcomed Lord Saltoun's motion, but deprecated the use of the word "failure" about a great service. But he agreed that there were things which could be improved, largely by coördination. One way in which the National Health Service Act had tried to correct discoördination was by the institution of health centres. But up to the present the dream of establishing those centres had failed nearly everywhere. In the intention of all who framed the National Health Service, health centres were an essential measure for coördinating the different regional authorities. Their development was stopped in 1948 owing to the need to limit building. In his view, health, and the proper provision of health, were as important as houses. Would the Government remove the restrictions that prevented health centres from coming into being? He also asked the Government to release the regional hospital boards from some financial controls. The Treasury rule of annual budgets was inappropriate, and more freedom of capital expenditure was needed to replace out-of-date buildings and equipment. Our only chance to save on pensions for the aged was to lengthen the average working life; and that depended, among other things, on health. When the Government received the report of the Guillebaud Committee he hoped they would take the opportunity to consider the administration as well as the finances of the N.H.S. Would they ask themselves whether a Minister with an ordinary central department of ordinary Civil Servants was the right organisation for running a great national industry to secure for the people of this country the means to health?

The Earl of CRANBROOK, who is chairman of the East Anglian Regional Hospital Board, thought that it would

be unreasonable to allow hospital authorities to carry over unspent balances of funds provided for running expenses, but he would like to see a carry-forward allowed for capital expenditure and ordinary maintenance expenditure on buildings. Constant pressure was brought on the Minister to provide more hospital beds, but Lord Cranbrook thought that the existing number of beds, certainly for acute cases, was sufficient to meet the need if proper use was made of them and there was a more rapid turnover. That could only be done if there were more home helps and home nurses. There must also be constant coöperation between the responsible authorities. An extraordinarily untidy machine had grown up, he thought quite fortuitously. The machine could be made to work by constant care and effort, but he thought the effort would be better spent if it were directed into making one machine instead of trying to make three work in together. As he saw it there were two possible solutions: the first was to hand the hospitals over to the local-health authorities and the second to hand the domiciliary services over to the hospital authorities. To hand the hospitals over to the local authorities would only be useful if the local authorities were to bear part of the cost on local rates. He was surprised to see a former Minister of Health¹ suggesting that local authorities should act as the Minister's agents in administering the hospitals while the Minister continued to pay the cost. An agent, he felt, could not publicly oppose the Minister. An agent could only resign, and as local authorities were run on party lines he felt the position would be untenable. For the same reason he disliked the suggestion that members of hospital boards and committees should be elected.

Lord AMULREE thought that elderly people suffered most from the lack of coördination between the health and welfare services. The National Health Service and National Assistance were two parallel lines, and like parallel lines they never met. The people who fell between the lines were those not strong enough to stand on either side—frail, infirm, and elderly people. There might be a good deal to be said for compulsory power to admit people to hospital, but there was also something to be said against it. As things were now the hospitals might become overfull, and overcrowded wards led to overworked staffs, and lack of proper treatment and nursing. If elderly people were treated properly in hospital and then discharged, beds would be available for all and emergencies would rarely arise. What he thought was needed was free exchange between welfare institutions and hospitals. Local authorities should provide more free accommodation for the frail and infirm and encourage the provision of domiciliary services. There was another reason why he pressed for coöperation. In 1901 the total number of people in the medical and auxiliary services was about 3000 per million of the population. In 1951 it had gone up to nearly 10,000 per million of the population. That was rather alarming, because it showed that the supply of staff was going to dry up. He had no wish to cut down the amount of work done; on the contrary, he was in favour of expanding it. But he would like to see whether something could not be done to prevent overlapping.

Lord MANCROFT, replying for the Government, could not accept Lord Saltoun's motion as it was worded, but he was prepared to accept it in spirit. There was no complacency about the health and welfare services in the minds of Ministers charged with administering them. Coördination was one of the greatest single problems of the service. Over 50,000 people were engaged in it and it was the third biggest concern in the country. At present coördination was secured by the interlocking membership of statutory bodies and joint standing committees. Like so many other problems it really resolved itself into one of human relationships. The suggestion that there should be all-purpose local authorities for all parts of the health and welfare services presented difficulties. Few local authorities had areas large enough for the planning, and perhaps operation, of a comprehensive hospital service. Nor was he convinced that all-purpose authorities would resolve the problem. In an authority of that size coördination of its different departments would not in practice be a great deal easier than the coördination of different authorities. In such a large

1. *Municipal Journal*, March 12, 1954; see *Lancet*, April 3, 1954, p. 72 i.

service there must be some central control, but the Minister was anxious that the spirit of the National Health Service Act should be generously interpreted and that local bodies with local initiative and responsibility should run the service in the way which best suited the needs of their locality.

Turning to the question of the aged; he suggested that we must make certain that they were not demanding of the State higher services than their needs really required. In 1911 there were 2 $\frac{3}{4}$ million people over pensionable age; in 1947 the figure had risen to 6 $\frac{1}{2}$ million, and in 1977 there would be 9 $\frac{1}{2}$ million. In England and Wales there were 54,000 staffed beds for the chronic sick and 3600 of those were empty for lack of nursing staff. But it was the turn-over of beds which really mattered. In 1951 the number of beds increased by 3.3%, while the number of patients treated increased by 10.1%. In 1952 comparable figures were 1% and 9%. Outpatient attendances had risen from 7000 in 1950 to 14,000 in 1952, inpatients rose from nearly 85,000 in 1950 to 103,000 in 1952, and the waiting-list had been kept fairly steady at about 9700. In residential accommodation provided by local authorities there were now some 66,000 places in England and Wales, and since the end of the war about 600 homes, with accommodation for about 18,000 persons, had been provided. Health centres, of which there were now four—in London, Bristol, Nottingham, and Faringdon—must, he admitted, still be regarded as experimental. They were expensive to build and had not been as popular either with patients or doctors as had been expected. An alternative was the establishment of group practices, and executive councils could now offer interest-free loans to groups of doctors to acquire or convert buildings for this purpose.

In his view, Lord Mancroft ended, the trouble with the Welfare State was that too many people worried about what they could get out of it and never bothered to think about what they could put into it. If the Good Samaritan on the road between Jerusalem and Jericho had stopped to look at the battered body of the wayfarer he would (if he had thought the way some people did now) have thought to himself, "Now I wonder whether it is the medical officer of health for Jericho whose job it is to look after that chap, or that of the Jerusalem City Council"; and he would have gone on his way.

QUESTION TIME

Distribution of Welfare Foods

Replying to a question, Major GWILYM LLOYD GEORGE, Minister of Food, said that the local health authorities had been invited to take over the responsibility for the distribution of welfare foods, other than liquid milk, when the local food offices were closed later in the year, as part of their duty under the National Health Service Acts to provide for the care of expectant and nursing mothers and young children. The associations of authorities covering England and Wales had already agreed to do so.

Contamination of Citrus Fruits by Thiourea

Replying to questions on the possible toxic effects arising from the contamination of citrus fruits by the use of thiourea, Major LLOYD GEORGE said that he was advised that the sale and importation of any article of food containing thiourea contravened the Preservatives in Food Regulations or the Imported Food Regulations respectively and that such sale and importation were therefore prohibited. Food and drugs authorities and port health authorities were so informed last January. The matter had been brought to the attention of the governments of the exporting countries.

Mr. A. W. J. LEWIS: Will the Minister consult the President of the Board of Trade with a view to taking some action? In the East End of London, and particularly in West Ham, these oranges are being sold at the moment and children are sucking the orange skins, which he will agree is very dangerous. I am informed that, unless he and his right hon. Friend implement the banning of these articles, the local authorities have not the powers to take action. Will he implement the banning? Major LLOYD GEORGE: At the moment the local authorities and the health authorities have full powers to deal with this because thiourea is a preservative which is not allowed. Therefore it is a matter for the courts to decide whether an offence has been committed. The prohibition on

imports is an important matter, and I am looking into it urgently to see what can be done if these regulations are not sufficient. I circularised all local and health authorities on Jan. 25, pointing out the danger of this particular spray. They have full powers to deal with it. All information which I have received from various parts of the country has come from local authorities.

Obituary

THOMAS CARNWATH

D.S.O., M.B. R.U.I., D.Sc. Belf., D.P.H.

Dr. Carnwath, whose death on April 2 we announced last week, was deputy chief medical officer of the Ministry of Health in the anxious years that preceded the late war. His wide knowledge of medical administration went back to the days of the Local Government Board, and after his retirement in 1940 he accepted the charge of reviewing Belfast's health services.

He was born in 1878, the son of J. Carnwath of Tyrone, and he was educated at Foyle's College, Londonderry, and Queen's University, Belfast. After he graduated as M.B. in 1900 he continued his studies at the University of Berlin. His early experience of public health was gained as an assistant at the Hamburg Institute of Hygiene and later at the Reichsgesundheitsamt in Berlin, and his first papers were written in German on such subjects as Hühner Diphtherie und Geflügel-pocken and the Technik der biologischen Untersuchung kleinster Blutspuren. He returned to this country to take the D.P.H. in 1906 and to become the assistant M.O.H. for Manchester, and later M.O.H. for Withington. He continued his biological studies, but his papers now dealt with such topics as a Bacteriological Survey of Belfast Lough and an Experiment on Quarantine of Shell Fish from Polluted Areas.

From Manchester he moved to London to take up an appointment as medical inspector under the Local Government Board, but his work there was interrupted by his war service. His cheerful gallantry in the early days in France in 1914 is described in the regimental history of the Honourable Artillery Company, to which he was attached as a surgeon captain. Later he served in the Balkans, and in 1918 he was awarded the D.S.O.

After the war he joined the staff of the newly formed Ministry of Health in the section of general epidemiology, where he was second in command to Sir George Buchanan. J. A. G., whose "early efforts" at the Ministry were in the main directed by Carnwath, recalls him as "genial, handsome, and debonair. He had great charm as well as great ability and wise judgment. For nine years I served under him; and he was always kind and ever cheerful."

After 1928 Dr. Carnwath was responsible for the complicated and technical work of administering the Therapeutic Substances Act, which controls the sale of biological products such as vaccines, sera, antigens, and insulin. During the immediate pre-war years he also took an important share in the Ministry's preparations for stockpiling medical supplies and creating a bacteriological service to meet an emergency. For both these tasks he was peculiarly fitted by his experience of laboratory work at Berlin and Hamburg. Besides these heavy official tasks he fulfilled many outside commitments. He was for a time lecturer on public health at St. Thomas's Hospital and an examiner for the Universities of London, Manchester, Birmingham, and Belfast. Many committees drew upon his experience, judgment, and common sense, and he was a member of the Army Hygiene Advisory Committee, the managing committee of the Bureau of Hygiene and Public Health

(Elliot & Fry)

of the Colonial Office, of the board of studies in hygiene and public health of the University of London, and of the National Radium Commission.

In 1935, the year in which the University of Belfast conferred on him an honorary degree, he was appointed deputy to Sir Arthur MacNalty, who writes: "My appreciation of Carnwath's wide knowledge of public-health problems and of his sterling qualities only increased with the years. In the strenuous years of preparation preceding the second world war and in the early months of the war itself, his help was ever forthcoming, and I felt it greatly when ill health compelled him to retire early in 1940. He went back to Northern Ireland; but I met him occasionally at the Athenæum, and I was glad to know his health had improved and that he was helping Northern Ireland's work in public health as an elder statesman."

W. D.-C., who succeeded Carnwath at the Ministry, also pays tribute to his qualities: "Soon after I joined the Ministry of Health in 1927 I became Tom Carnwath's assistant, and his kindness, helpfulness, and good advice quickly made us the firm friends that we always remained. He had all the finest characteristics of the Northern Irish: quiet determination, cheerful acceptance of responsibility, and a hatred of humbug. His quiet almost casual manner cloaked a shrewd intellect, thoroughness in all he undertook, invariable consideration for others, and a keen sense of humour. He had the happy knack, so valuable to an administrator, of quickly seeing the most practical solution of any problem. His philosophical outlook enabled him to bear the disappointments of life with equanimity and to enjoy his retirement in his beloved County Antrim."

Dr. Carnwath married in 1908 Margaret M'Kee of Belfast, who survives him with two sons.

HENRY WILLIAM MARETT TIMS

O.B.E., M.A. Camb., M.D. Edin.

DURING the early years of the century Dr. Marett Tims was well known at many London colleges and medical schools as a teacher and examiner in anatomy and biology.

He was born in Calcutta, the son of Dr. T. Lamb Tims, and was educated at Reading School. After graduating at Edinburgh University in 1887 as M.B., with honours in almost every subject, he held demonstratorships in anatomy and physiology in Edinburgh before he came to England in 1889 to continue his postgraduate studies at St. Thomas's Hospital and the University of Cambridge. In 1890 he took his M.D. with commendation, and two years later he was appointed lecturer in biology and comparative anatomy at Westminster Hospital Medical School. Soon afterwards he was appointed reader in zoology at Bedford College for Women. About this time he became an examiner in physiology and biology for the Society of Apothecaries and in elementary biology for the Conjoint Board. He also held a demonstratorship in human morphology in the University of Cambridge, and in 1901 he took his B.A. (research) at King's College, Cambridge. In the same year he was appointed lecturer in comparative anatomy and biology at Charing Cross Hospital Medical School, and in 1908 he joined the staff of the Royal Veterinary College as professor of biology. During the 1914-15 war he left these multifarious duties to serve in the R.A.M.C. with the rank of lieutenant-colonel. For his work in these years he was appointed O.B.E. in 1919, and in 1920 he was awarded the order of St. Sava of Yugoslavia.

As his career suggests, Dr. Tims's experience was varied and wide. He was a recorder and vice-president of section D of the British Association, and his papers to the association included one on the development, structure, and morphology of the scales in teleostean fishes. But no aspect of comparative anatomy held his interest so greatly as that of the teeth and their homologies, which had been his main preoccupation since the 'nineties when he had read papers before the Linnean Society on tooth genesis in the Canidae and the Cavidæ. It was therefore appropriate that after the war he was appointed lecturer in comparative dental anatomy at the Royal Dental Hospital and was chosen as scientific editor of *Tomes's Dental Anatomy*. He was responsible for the 7th and 8th editions, and C. B. H., who shared in this task, writes: "Marett Tims entered with zest,

and effectively, into the arguments about polyphyodontism and tooth-vestiges and the evolution of the forms of teeth. While rejecting Kukulenthal's idea that molars represent the fusion of teeth belonging to two successive series, he expressed his opinion that fusion of two teeth anteroposteriorly in the same series may occur. He was absorbed in the evolution of dentition, and no other authority was in the same rich position to re-edit Tomes's manual, which was first published in 1876. No further edition has been published, and no new publication has supplanted his eighth edition which remains the standard work of reference in comparative dental anatomy."

In 1888 he married Alice Maud Mary, the daughter of Lieut.-Colonel Alexander Findlay, acting governor of Sierra Leone and the Gambia. Dr. Marett Tims survived her by four years and died on March 4, a few days before his 91st birthday. They leave a son and a daughter.

Diary of the Week

APRIL 18 TO 24

Tuesday, 20th

SOCIETY FOR THE STUDY OF ADDICTION
8 P.M. (11, Chandos Street, W.1.) Mr. Derek Curtis-Bennett,
q.c.: Alcoholism and the Law.

Wednesday, 21st

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of Comparative Medicine.* Prof. L. P. Garrod: Effects of Antibiotics on Body Functions of Man and Animals. Prof. Alan Kekwick: Pharmacology of Some Commonly Used Antibiotics. Dr. W. S. Gordon, Mr. J. H. Taylor: Growth-Promoting Effect of Antibiotics—their Possible Modes of Action. Mr. S. K. Kon, D.Sc.: Function of Antibiotics in Animal Nutrition.
8.15 P.M. *Section of General Practice.* Dr. Oliver Plowright, Dr. Wilfrid Sheldon, Mr. R. J. Cann: Tonsils and Adenoids.

Thursday, 22nd

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. D. J. Browne: Principle of Controlled Movement in Orthopaedics. (Hunterian lecture.)
ROYAL SOCIETY OF MEDICINE
8 P.M. *Section of Urology.* Mr. F. G. Smiddy: Hyaluronidase and Urinary Stone. Mr. A. W. Badenoch, Mr. A. G. Dingloy: Influence of Hyaluronidase on Renal Lithiasis. Mr. Basil Page, Mr. Ashton Miller, Mr. D. T. H. Paine: Vasotomy. Mr. D. St. Clair Henderson: Vesico-ureteral Reflex.
8.15 P.M. *Section of Obstetrics and Gynaecology.* Mr. C. M. Gwillim, Dr. H. J. Wallace, Dr. Magnus Haines: Leucoplakia and Allied Conditions.
CHADWICK LECTURE
5.30 P.M. (26, Portland Place, W.1.) Dr. C. Banning (Netherlands): Antenatal, Natal, and Postnatal Care in the Netherlands.
UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Mr. J. Bruce: Surgery of Small Intestine.

Friday, 23rd

OSLER CLUB OF LONDON
7.45 P.M. (11, Chandos Street, W.1.) Mrs. Marie Stopes, D.Sc.: History of Contraception.

Appointments

BARNES, JOSEPHINE, D.M. Oxf., M.R.C.P., F.R.C.S., F.R.C.O.G.: part-time asst. obstetrician and gynecologist, Charing Cross Hospital, London.
BURNS, J. P. J., M.C., M.B. Belf., D.P.H.: senior asst. M.O., area No. 6, Middlesex.
DONELAN, M. J., M.B. N.U.I., D.P.H.: M.O., area No. 1 (Tredegar and Rhymney urban districts), Monmouthshire.
EDMONDSON, MARGARET M., M.B. Edin.: asst. M.O.H. and school M.O., Grimsby.
FOURACRE, A. J., M.R.C.S.: factory doctor, Withernsea, Yorks.
FOWLER, P. B. S., D.M. Oxf., M.R.C.P.: part-time asst. physician, Charing Cross Hospital, London.
PICKLES, A. N., M.B. Leeds, D.P.H.: district M.O.H. and asst. county M.O., Kettering.
Liverpool Regional Hospital Board:
BRYSON, J. R., M.B. Glasg., F.F.A. R.C.S.: consultant anaesthetist, Clatterbridge General Hospital.
PRINSELY, D. M., M.D. Durh.: senior R.M.O., Barrowmore Hospital.
THEOP, EDITH M., M.B., B.Sc. Manc., D.P.M.: whole-time asst. psychiatrist, Winwick Hospital.
South-Western Regional Hospital Board:
BRAMLEY, P. A., M.B., R.D.S. Birm., F.D.S. R.C.S.: consultant dental surgeon (part-time), Plymouth clinical area.
TROBRIDGE, G. F., M.B. Birm.: registrar in diseases of the chest, Hawkmoor Chest Hospital, Bovey Tracey, S. Devon.
TULLOCH, L. G., M.D. Aberd.: senior registrar in dermatology, Bristol clinical area.

Notes and News

WORLD HEALTH ORGANISATION

THE fifth year of W.H.O. is described by the Director-General, Dr. M. G. Candau,¹ as a period of "growth, adjustment, and consolidation" but also of "extremely serious and prolonged financial crises." The cut in the proposed United Nations Technical Assistance funds from an expected \$9 million to an eventual \$4.5 million resulted in curtailment or cancellation of many projects. Nevertheless, there were many substantial achievements. More than 330 health projects were helped in seventy-four countries; and 106 of these were completed during 1953. The campaign against communicable disease was extended; campaigns for control of malaria were carried on in twenty-one countries; 15 million persons were examined and 4 million treated for yaws and venereal diseases; and in twenty-four countries assistance was given for anti-tuberculosis measures. Health education has continued to be one of the major activities of W.H.O., in accordance with its consistent policy of helping underdeveloped countries to become self-supporting in medical services. 894 fellowships for study abroad were granted to health workers, in addition to those granted for local studies; the exchange of scientific information was encouraged by provision of teams of visiting medical experts, by regional or international medical conferences, and by supplying teachers or equipment to medical schools.

The World Health Day, on April 7, was this year devoted to the theme *The Nurse, Pioneer of Health*. Speaking in London on this occasion, Dr. Candau said that the basic aim of W.H.O. was to help countries to strengthen their national health services so that they might take the next feasible step forward in their development. It could be said, with some justice, that W.H.O. was, in the end, a self-liquidating organisation in that its task was to remove, in the largest possible measure, the need for its services. In the Western world the habit had become rather widespread of referring to certain countries as "underdeveloped." "There is always a danger in simplification; and the particular danger in this case is that it can lead to those feelings, and consequently expressions, of national superiority which can make international co-operative action well-nigh impossible. It is true that the Western communities are farther ahead along the road to national health and well-being than are, for instance, their brothers in Asia; but it is a chastening experience to consider just how short is the distance which divides them. . . . Everybody in this great city takes the existence of a supply of safe drinking-water for granted. Yet exactly one hundred years ago—that is, within the lifetime of the grandfathers of many now listening to me here—London possessed no general water-supply. One small section . . . was served by a pump which brought up water from a well in Broad Street . . . in 1854 this well, polluted by leakages from a neighbouring cesspool, brought death, in the form of cholera, to six hundred and sixteen people within the short space of two months."

Dr. Candau concluded by saying that the World Health Assembly next month would be asked to increase the effective working budget of the Organisation from the previous year's figure of \$8½ million to \$10,300,000. The United Kingdom was the second largest contributor, after the U.S.A.; and the proposed increase would raise the annual contribution per head of population in the United Kingdom from 1½d. to 2d.

HUNTERIAN INFLUENCE IN EXETER

At a meeting of the Devon and Exeter Medico-Chirurgical Society on March 18, Mr. Norman Capener, the president, spoke of the Hunterian Influence in Exeter, relating his talk particularly to the medical school which flourished there during the first half of the 19th century. The school failed to survive the Medical Act of 1858, but while it lasted it included among its teachers outstanding figures, many of whose portraits are displayed in the board room of the Royal Devon and Exeter Hospital. As a background to the Hunterian tradition, the President discussed the influence of Cullen, Cheseldon, and Pott, and the impact of the Hunters upon their pupils, and their pupils' pupils. Nurtured in the Hunterian tradition was John Haddy James, a favourite pupil of John Abernethy. He was born in Exeter and with Samuel Barnea, another Exeter Barts man, he was a leader in the

development of the Exeter school of medicine. He joined the staff of the Devon and Exeter Hospital after serving with Wellington at Waterloo, and two years later won the Jacksonian prize for an essay on inflammation. He invented many interesting mechanical devices and is noteworthy for having introduced continuous traction in the treatment of fractures. He was one of those who assisted Charles Hastings, of Worcester, in the foundation of the Provincial Surgical and Medical Association which later became the British Medical Association. James became its president in 1842, and the next year was one of the original fellows of the Royal College of Surgeons of England under its new charter. By 1854 the medical school had a close liaison with the Royal College of Surgeons. It had its museum, lecture-room, dissecting room, and laboratory and a magnificent library.

A HOME FOR BACKWARD CHILDREN

St. Christopher's Trust, formed by the parents of mentally handicapped children in 1951, has opened a home at Glossop in Derbyshire. The house, which is called Redcourt, is a large one, with extensive grounds; and though at present there are only six children (aged 8–14), it will be able to take about fifty receiving residential training. The trust is running Redcourt unaided for 12 months, after which time it should be eligible for grants from local authorities.

N.H.S. AMBULANCE SERVICES

THE demands on these services continue to rise¹ and a recent memorandum (H.M.(54)33) from the Ministry of Health announces that local health authorities and hospitals are being asked to co-operate in local surveys to be undertaken by an ambulance adviser and a medical officer for the Ministry. Ways of securing better co-ordination and more economy in the use of ambulances are to be sought.

The Minister suggests that local authorities, when replacing vehicles, should bear in mind the advantages of ambulances for sitting patients which will accommodate a stretcher case if need be. They should also remember that travel by rail is not only cheaper but often more suitable for both types of case, and that stretchers suitable for transfer direct from ambulance to train are now available. Greater operational efficiency and economy in use of vehicles and staff is usually possible if all calls for ambulances go through ambulance control stations, especially where there is radio communication between these and individual ambulances. The duplication of ambulance services and inequalities between charges of various ambulance authorities should be reduced by closer co-ordination between them.

ALUMINIUM HOSPITAL BUILDINGS

At the British Industries Fair to be held at Earls Court, London, from May 3 to 14, the Bristol Aeroplane Company (Weston) Ltd. are showing a 'Bristol' permanent aluminium hospital building. This consists of a reception lounge 24 ft. square by 9 ft. high flanked by a complete operating-suite 48 ft. long, 32 ft. wide, and 12 ft. high, comprising a theatre and four ancillary rooms. The company has already built over twenty hospitals and nurses' homes in Australia, including the largest prefabricated hospital in the world, the Manly District Hospital, Sydney. The advantages claimed for this method of unit construction include speed of erection, saving in site labour and designing time, dry construction, and easier installation of services.

STANDARD FOR TRANSFUSION EQUIPMENT

THE new British Standard for transfusion equipment (B.S. 2463: 1954) has been prepared to cover the requirements of the National Blood Transfusion Service and the Armed Services. The design of the bottle is that of the M.R.C. bottle, but without the "waist," which, though useful in providing a firm grip, has proved undesirable during freeze-drying operations. Attention has been paid to the need for interchangeability with similar equipment in other countries. Certain essential dimensions, such as those of the neck of the bottle, of rubber tubing, and of olive mounts, have been arrived at, and cognisance has been taken of discussions at a meeting of the transfusion equipment technical committee of the International Organisation for Standardisation held in London in 1952. In certain items—namely, the drip-counter, the filter-chamber, and the rubber closure—the design has not been specified but performance requirements are given instead. Only tubing made from natural rubber has been

1. The Work of W.H.O., 1953: Annual Report of the Director-General. H.M. Stationery Office, 1954. Pp. 190. 10s.

1. See *Lancet*, 1953, i, 1316.

included in the standard since it is considered premature to include plastic tubing in the specification at this stage. Copies of this standard (3s. each) may be obtained from the British Standards Institution, Sales Branch, 2, Park Street, London, W.1.

OPERATION ON CONJOINED TWINS

The Conjoined Twins of Kano (16 mm., sound, colour, 40 minutes) is a film record of the operation at Hammersmith, at the end of last year, to divide conjoined twins. A brief history of the birth of the twins is followed by details of the examination of them, with special reference to the linking bridge and the structures it may contain. In this sequence there is a methodical development of thought from the examination by inspection and palpation to the more complex investigations by radiography and radioactive-isotope circulation tests, including a summary of the calculations by which the circulatory interchange between the twins was estimated. The operation itself is shown in great detail, including the instruments; skin preparation, anaesthesia, and intubation of the two infants; incision; operative technique; and precautions taken. Intelligent camera-work and skilful editing make clear every feature. The film ends with shots of the surviving child with his mother and of the necropsy specimen from the other. The bulk of the exposition is carried by the commentary, expertly delivered by Alvar Liddell, while the picture illustrates and often supplements what is said. The production, by Stanley Schofield, is of high standard. The medical adviser was Prof. Ian Aird.¹

University of London

Dr. F. E. Camps, lecturer at the London Hospital Medical College, has been appointed to the part-time university readership in forensic medicine at the college.

Mr. G. E. Francis, F.R.C.S., senior lecturer at St. Bartholomew's Hospital Medical College, has been appointed to the university readership in biochemistry at the college.

University of Leeds

Dr. Alfred Blalock, surgeon in chief to the Johns Hopkins Hospital, Baltimore, will deliver the Moynihan lecture at the University Union on Friday, May 14, at 3.30 P.M. He has chosen as his subject the Expanding Scope of Cardiovascular Surgery.

University of Edinburgh

On May 5 Prof. H. K. Beecher (Harvard Medical School) will deliver a MacArthur postgraduate lecture on Resuscitation and Other Early Care of the Severely Wounded Man. On May 6 Prof. Gerhard Domagk, director of the research laboratories for pathology and bacteriology of Farbenfabriken Bayer, is to give a Cameron lecture on Chemotherapy in Tuberculosis. On May 11 Dr. Ewart A. Graham, chairman of board of regents, American College of Surgeons, is to deliver the second Sir John Fraser lecture on Cancer of the Lung. All these lectures will be held at 5 P.M. at the University New Buildings, Teviot Row.

Royal Society

Sir Howard Florey, F.R.S., will deliver the Croonian lecture on Thursday, May 27, at the society's rooms, Burlington House, Piccadilly, London, W.1, at 4.30 P.M. He will speak on Mucins and the Protection of the Body.

Society of Medical Officers of Health

Dr. Frederick Hall has become part-time medical secretary of this society. Mr. G. L. C. Elliston has given up his post as secretary to give all his time to the editorship of *Public Health* and the *Medical Officer*.

Naval Medical Compassionate Fund

A meeting of the subscribers of this fund will be held at 2.30 P.M. on April 30 at the Medical Department of the Navy, Queen Anne's Mansions, St. James's Park, London, S.W.1, to elect six directors.

St. John Ambulance Brigade

A conference for surgeons, nursing officers, and non-medical officers of the brigade is to be held at the Cairn Hotel, Harrogate, from Friday to Sunday, April 23 to 25. The speakers will include: Major A. C. White Knox, the surgeon-in-chief, Dr. A. D. D. Broughton, M.P., Prof. Cyril Polson, and Dr. C. C. Boley.

Royal College of Surgeons of England

At a meeting of the council held on April 8 the honorary fellowship was conferred on Dr. G. Gavin Miller of Montreal. The following were elected to the fellowship without examination as medical practitioners of at least 20 years' standing: Mr. J. W. H. Grice (Tunbridge Wells), Mr. D. M. E. Thomas (Sully, Glam.), Prof. G. Hadfield (London), Prof. J. Trueta (Oxford), and Mrs. D. R. Campbell (Coventry). Mr. W. A. Jackman (Bristol) and Mr. R. R. Simpson (Hull) were admitted to the fellowship ad eundem. Dr. W. D. M. Paton (University College Hospital Medical School) was admitted as the first professor of pharmacology.

The Jacksonian prize for 1953 was awarded to Mr. J. H. Peacock. The first Mitchiner medal was awarded to Brevet Colonel H. D. Chalke, and the first Lady Cade medal to Squadron-Leader R. R. L. Fryer. Prof. Martin A. Rushton (Guy's) was awarded the John Tomes prize. A Hunterian lectureship was awarded to Prof. Milroy A. Paul (Ceylon). The council selected Diaphragmatic Hernia as the subject for the Jacksonian prize for 1955.

Diplomas were granted jointly with the Royal College of Physicians to the following:

D.C.H.—Delldre M. Airey, Enld Atkins, Herman Aufrechtig, Doris M. Beaton, Elaine M. Bolton, Elizabeth F. Bennett, Jagri Ram Bhatia, Flora M. Bisset-Smith, Audrey M. Bolton, E. M. Broadfoot, J. A. Browne, D. W. Bull, June M. Burger, A. P. Camilleri, Kai Hang Chau, J. A. Cheese, Omana Amma Cheriyan, Emanuel Chigier, J. H. Clyde, G. J. Cousins, Mary Crawford, Joan M. St. V. Dawkins, Sooba Rama Deenadayalu, J. M. Doyle, Catherine M. Durkin, J. G. Edgar, C. P. E. Elliott-Binns, J. W. Fisk, D. M. Fraser, Shiba Prasad Ghosal, Sheila M. Gough, Margaret L. Gladstone, Isobel H. Grant, Sripal Tilak Gunewardene, Ann M. Haines, Margaret E. Hall, Mary Hallowell, M. J. T. Hewetson, Sai Kong Ho, Kathleen A. Hockey, K. S. Holt, Megan D. M. Johnson, Jocelyn Johnston, Premalal Kapur, Pathmaranie Kathiravelu, R. E. Kottler, Sylvia Lath, J. B. Lewis, Melvin Lewis, Siew Whye Loh, G. C. Love, Margaret Luig, M. F. McDowall, Thomas McKendrick, Sheila L. McKinlay, Sohan Singh Manchanda, Cicely J. Millbank, Rhona E. Morgan, Marion E. Morris, Marion B. Morton, Chitra Mukherjee, B. K. A. Muller, N. V. O'Donohoe, R. M. Oliver, Ida S. Paranjoti, Hawa Patel, G. N. St. J. Penney, Jean Poole, Frances E. Powell, Edith I. Proctor, S. D. Roche, Sonia Rollin, Carol J. Rubidge, H. H. Shawdon, Isabel G. Smith, M. H. Southall, Joyce K. Starkie, Joan V. Stavert, Kenneth Stewart, Mary Sugden, Majuree Sundaravej, C. G. W. Sykes, I. G. Thomson, J. N. Ure, Denorah Vardy, Claudine M. R. Vesey, I. S. Wallman, Ruth M. Walters, Moganat Arashat Warley, S. M. D. G. R. Wijegunaratne, P. S. W. Wilkins.

D.Phys. Med.—D. J. E. Cheshire, P. R. Travers.
D.O.—J. A. Akingbehin, M. R. Ashbridge, Mohamed Hassan Ashruff, D. J. Bowerman, George Davidson, Mohammad Siddiq Faridi, K. C. Garg, Harry Hardy, B. A. E. Harley, Sukhalal Udhoji Joshi, Akil bin Abdul Kadir, R. C. K. Loh, Marguerite C. Macdonald, Laurel J. MacIntosh, Mazharul Haque Malik, D. L. E. Payne, R. A. Quesada-Guardia, J. N. Rohatgi, Satyasinha Roy, G. S. Sandhu, Gurbakhsh Singh, K. S. Subramaniam, A. A. Tye, J. H. W. Wessels.

D.T.M. & H.—J. C. Aickin, F. L. Ashworth, A. S. Beare, Chanindhara Bhamarasuta, N. K. Bharucha, Z. M. A. Cader, A. T. Cook, T. M. Desai, J. K. Gajjar, G. H. K. Gentile, J. E. J. Hurman, Samrit Jatinandana, A. C. Kail, Ahmad Mohammed Khatib, Y. J. Kiladjan, A. G. Lelshman, W. S. Millar, H. R. Miller, K. P. Milne, Adam Muir, I. G. Murray, Leslie No Onha, Magdalen K. E. Oberhoffer, Mohan Kumar Panikkar, Kanu Hirabhai Patel, H. N. Ray, Werner Rollnhoff, P. D. Scheffel, E. K. Tagboto, Paul Yates, Ponniah Yoganathan.

British Association

This year the annual meeting of this association will be held at Oxford, from Sept. 1 to 8, under the presidency of Dr. E. D. Adrian, O.M., F.R.S.

Hunterian Society

The gold medal of this society for 1953 has been awarded to Dr. J. Lipsey (Littlehampton), and a proxime accessit award has been made to Dr. B. C. Zoob (Battersea).

The subject for the 1954 essay is Management of the Climacteric in General Practice. Further details may be had from the hon. secretary, Mr. Alec A. Badenoch, 110, Harley Street, London, W.1.

International Union of the Medical Press

The second congress of the union is to be held in Turin on May 30. The speakers will include Dr. H. Fiessinger (*Le Monde*), Dr. J. Lederer (*Association Presse Médicale Belge*), Dr. J. J. Gillon (*Concours Médical*), Dr. H. A. Clegg and Dr. J. W. P. Thompson (*British Medical Journal*), and Dr. G. C. Angela (*Minerva Medica*). Further particulars can be had from the Secretary of the Congress, Dr. F. Gavosto, Corso Bramante 83, Turin, Italy.

CORRIGENDUM: *Abnormal Nerve Impulses*.—In this leading article (March 27, 1954, p. 660) footnote 6 should read: "Lepeschkin, E. *Amer. J. Med.* 1954, 16, 73."

THE RIDDLE OF THE MAST CELLS

A TRIBUTE TO PAUL EHRLICH *

JAMES F. RILEY

M.D., F.R.C.S.E., D.M.R.T.

From the Department of Radiotherapy, the Royal Infirmary, Dundee, and the Medical School, University of St. Andrews

ON Jan. 17, 1879, the Physiological Society of Berlin heard a remarkable paper by a remarkable young man. The speaker was Paul Ehrlich,¹¹ a newly qualified doctor; his subject a granular cell of the connective tissues, discovered by him during his student days,¹⁰ for which he proposed the name "mast cell" (*Mast*=food) because he had found them most commonly in those connective tissues whose nutrition appeared to be enhanced. Later he discovered somewhat similar cells in the blood,¹² but he was quick to realise that whereas the comparatively rare blood mast cell (basophil, mast leucocyte) takes origin in the bone-marrow, the more common tissue mast cell is born, lives, and dies in the connective tissues. The similarity of the two types of mast cell lies in their content of cytoplasmic water-soluble granules which stain metachromatically with certain basic dyes.

In view of Ehrlich's later work it is interesting to see in this his first piece of research the beginning of that golden thread which runs through the whole of his working life—the search for "specific affinities" between living protoplasm and known chemicals such as the dyes and drugs that were then appearing. That the biological action of a drug is a direct consequence of its molecular architecture is now a pharmacological axiom so firmly established as to pass without comment. In Ehrlich's day of empirical treatment this concept of chemotherapy was new.

It is said²³ that Ehrlich's curiosity was first aroused in the laboratory in which his cousin Karl Weigert, the histologist, was working. There, chancing to look through a microscope at a prepared slide, Ehrlich fell to speculating on the mechanism which determines the staining characteristics of cytoplasm and nucleus. It must be, he argued, that the chemical configuration of the protoplasm is the opposite of that of the dye; the two fit together like pieces of a jigsaw puzzle or (in the more classical analogy) like a key in a lock. Reasoning thus, Ehrlich conceived that it might be possible to synthesise a dye with affinities specific for the bacterial cell and thereby provide the means of directing a dye or drug selectively to its target in the body.

Fired with this idea, he obtained samples of the latest commercial dyes from the great German chemical dye manufacturers who were then turning to such profitable account Perkin's original discovery in Manchester of the first synthetic dye, mauve. On applying these new dyes to fresh fragments of tissue, Ehrlich observed that the cytoplasm of certain connective-tissue cells contains granules with specific affinities for such basic dyes as dahlia, toluidine-blue, methylene-blue, and neutral red. These granular cells were particularly common around small blood-vessels and evidently formed part of the heterogeneous collection of "embryonal cells" described by his teacher Waldeyer.⁵²

Not the least of Ehrlich's attributes was his intuitive understanding of the limitations of the experimental methods of his day. Having discovered and named the mast cells, and having described clearly their morphology, staining properties, and distribution, he left it to others to elucidate the chemical nature of their granules, contenting himself by expressing the hope that some day an interesting function would be found for these mast

cells of his.¹¹ My purpose here is to trace the further story of the mast cell and to see to what extent his hopes have been fulfilled.

The Mast Cell in Evolution

For the sixty years which followed Ehrlich's discovery of the mast cell, research on this subject remained almost entirely histological; and it is of interest to see how far down the evolutionary scale mast cells can be demonstrated.

The volutin granules of protozoa, yeasts, and bacteria have been thought by some to be the homologues of the mast-cell granules in higher organisms.⁵³ Recent work casts doubt on this view.⁴⁹ Nevertheless, in such lowly forms of life as the sponges,⁶ starfishes, sea-urchins,²⁴ and molluscs²⁵ there are already cells in the mesenchyme with basophilic metachromatic granules in their cytoplasm—by definition mast cells. At the level of the crustaceans mast cells can readily be demonstrated, as Hardy¹⁶ showed, around the arterioles of the crayfish. Many workers have failed to appreciate the high content of mast cells in the tissues of the fish, because here (as in the rabbit) the granules are extremely soluble in water and are lost when the specimen is placed in a watery fixative or stain. In the salmon mast cells are found enmeshed in the collagenous "stratum compactum" in the wall of the gut.¹⁴ They are common in the tissues of the reptiles and amphibia.²⁷

Among the warm-blooded vertebrates mast cells occur predominantly in the loose connective tissues and especially around the smaller blood-vessels.^{2, 10} They are virtually absent from the central nervous system¹⁷ though present in the sheaths of peripheral nerves.⁴⁴ In general the parenchymatous organs are poor in mast cells except in the connective tissue of the capsule and trabeculae.^{19, 29, 51} A noteworthy exception to this is the widespread distribution of mast cells throughout the parenchyma of the dog's liver.³⁰

Mast Cells in Pathological Conditions

In choosing the name "mast cell" Ehrlich¹¹ was influenced by his finding of a high mast-cell content in connective tissues subjected to lymph stasis—especially, as he said, in chronic inflammation and in the environs of tumours.^{10, 12} In the selective lymphatic blockage of elephantiasis the hypertrophied connective tissue is packed with mast cells,² and a similar histological picture on a smaller scale is seen in young well-vascularised keloid.⁴⁷

Tumours composed of mast cells are rare, occurring most commonly in dogs^{2, 29} and occasionally in cattle.¹⁵ One example has been reported in man.¹⁸ The common mast-cell lesion in man is the skin disease of childhood, urticaria pigmentosa,⁵⁰ in which focal collections of mast cells are seen in the dermis. Occasionally urticaria pigmentosa presents as a solitary tumour-like nodule^{9, 46}; very rarely indeed as a generalised mastocytosis.¹³ Finally we may note that an increase of the blood mast cells occurs in chronic myeloid leukaemia, the condition in which Ehrlich¹² first found mast cells in the blood. True basophilic leukaemia is extremely rare.⁷

The Mast Cell and Heparin

In 1937 Michels²⁷ compiled his monumental review on the mast cells, summarising the literature and citing 25 unresolved hypotheses concerning the function of these cells. Ironically enough in that same year reports came from Scandinavia that the "riddle of the metachromatic granules in the mast cells of Ehrlich" had been solved.^{19, 22, 23}

Swedish workers have been traditionally interested in anticoagulants, and Jorpes²³ and his colleagues in Stockholm had long been working on a powerful anti-coagulant first isolated from dog liver and hence called

* Based on a postgraduate lecture delivered in the Medical School, Dundee, on Nov. 19, 1953.

Fig. 1—Suggested formulae for heparin and hyaluronic acid. (Redrawn from Burkl 1952.)

“heparin.” Heparin proved to be a mucopolysaccharide rich in sulphate groups, and on finding that heparin stained metachromatically with toluidine-blue Jorpes requested his histological colleagues to search the tissues for metachromatism as a possible clue to the site of formation of heparin.¹⁹ (Cartilage, of course, stains metachromatically, but cartilage has no anticoagulant activity.) It was then that the histologists rediscovered the metachromatic granules in the mast cells and Jorpes was able to show that there is a good correlation between the mast-cell content of a particular tissue and the amount of heparin that can be extracted from it. Point has been given to this work by the recent demonstration of exceptionally high anticoagulant activity in a mast-cell tumour³²—a small mastocytoma from a dog yielding fifty times as much heparin as the animal's whole liver, the organ from which heparin received its name.

This newly discovered function seemed to provide an obvious and teleologically satisfactory explanation of the perivascular location of the mast cells. Mast cells are perivascular because they produce heparin which they pour into the blood-stream. It was a study of this very relation of mast cells to blood-vessels which led to the discovery of another and completely different function of the tissue mast cell.

The Mast Cell and Histamine

According to Quensel,³⁴ mast cells occur almost exclusively around capillaries. However, examination of tissues from the rat³⁵ revealed that tissue mast cells commonly arise from undifferentiated precursor cells in the adventitia of somewhat larger vessels with obvious muscle coats. As the cells mature and fill with metachromatic granules they tend to move away from the vessels into the nearby connective tissues and there slowly lose their granule substance. Whatever is released from these granules would appear to be destined for action within the tissues rather than within the blood-stream.

In the search for some function of mast cells other than the production of heparin, it was recalled that a simultaneous release of heparin and histamine could occur from the liver of the dog,⁴³ and it thus seemed of interest to see if histamine as well as heparin might perhaps come from the tissue mast cells.

The effects of chemical histamine-liberators were first studied,³⁶ and it was found that when a rat is killed quickly by an intravenous dose of fluorescent histamine-liberator the fluorescence is at first sharply localised to the mast cells, especially within the loose tissues of the peritoneum. Thereafter the mast cells break up, and when this has happened the histamine content of the tissue is found to have fallen.³⁹

As with heparin,²³ there is also a good correlation between the histamine content of a particular tissue and the number of mast cells which it contains,³⁷ and this is especially evident when pathological tissues rich in mast

cells are examined.³⁸ The lesions of urticaria pigmentosa contain two and a half times as much histamine as the adjacent skin, and with this we may correlate the well-known dermatological observation that light stroking of one of these lesions rapidly produces a reactive weal limited to the lesion itself. The mast-cell content of mouse skin increases on painting with a carcinogenic hydrocarbon, and as this takes place the histamine value also rises. Mast-cell tumours contain exceptionally high quantities of histamine, a pleomorphic mast-cell lesion from a child yielding the unprecedented value of nearly 1000 µg. (1 mg.) histamine per gramme of tissue.

Thus mast cells appear to be as rich in histamine as they are rich in heparin.⁴² But when we remember that mast cells are plentiful in lower organisms which lack a blood-vascular system, and that even in higher animals the cells appear regularly to be associated with the tissues rather than with the blood-vessels, we have grounds for doubting whether either heparin or histamine completely answers Ehrlich's riddle. Indeed it seems possible that the production of both heparin and histamine are but part of the mast cell's function, and that there remains unproved a third function which is probably a fundamental interaction between the mast cell and the connective tissues. Such views are admittedly speculative, but at least they may point the way to a further chapter in the story of the mast cells.

Heparin and Hyaluronic Acid

Heparin is a polymer, compounded of disaccharide units consisting of glucuronic acid and an amino-sugar, glucosamine.²³ In this respect heparin closely resembles another naturally occurring polymer of great physiological interest, hyaluronic acid.⁴ But whereas the amino-sugar of hyaluronic acid is acetylated, that of heparin is sulphated (fig. 1). It is the sulphate moiety especially which confers on the heparin molecule its anticoagulant

Fig. 2—Diagram to show the participation of the mast cells in the dynamics of the connective tissues. Mast-cell content is indicated by the signs 0 to +++; the cross-hatching indicates metachromatic ground substance.

property.²³ On the basis of the similarity of composition of heparin and hyaluronic acid, Asboe-Hansen¹ in Denmark now suggests that the heparin or a heparin-like precursor secreted by the mast cells into the tissues is there gradually desulphated and becomes hyaluronic acid. If the recent formulæ for heparin and hyaluronic acid are correct, so simple a conversion is unlikely; the essential building blocks are there but the internal molecular linkages are different.⁴ Nevertheless, the high mast-cell content of loose fibrillary connective tissue generally,⁴⁶ and particularly of those specialised clefts in the embryonic mesenchyme which become joints,¹ and the curiously rich mast-cell population of serous membranes and organ capsules^{19 39 51} (sites normally coated with a surface film of viscous lubricating fluid), all seem to confirm the view of Staemmler⁴⁶ that the mast cells are "unicellular glands of the connective tissue which through their activity produce the mucinous interfibrillary cement."

The participation of the mast cell in the dynamics of the connective tissues is illustrated in the sequence of events shown diagrammatically in fig. 2. Mast cells are

Fig. 3—Mast cells in a fresh spread of ox peritoneum; fixed alcohol, stained toluidine-blue. The cytoplasm is packed with dark metachromatic granules ($\times 535$).

not present in the early embryo, and appear in their characteristic locations only towards the end of embryonic life when they rapidly fill with granules.²⁶ If, however, the connective tissue is later subjected to trauma—mechanical, chemical, thermal, bacterial—whereby an "acute watery œdema"⁸ is produced, the mast cells promptly release their metachromatic substance into the tissues⁴⁸ (figs. 3 and 4). The appearance of tissues thus mobilised for regeneration and repair closely resembles the histological condition of embryonic connective tissue.²⁰ Fibroplasia of shorter or longer duration follows, and, as recognisable collagen begins to take its shape, mast cells once more appear in the reactive zone.^{31 46} Should fibroplasia be unduly protracted, as in chronic inflammation, the mast-cell population further increases^{11 21}; and in conditions of chronic lymphatic obstruction, in which the tissue spaces remain loaded with protein-rich œdema fluid, both mast-cell hyperplasia and connective tissue hyperplasia become extreme.² The end-point of the sequence is reached with the formation of avascular scar tissue in which neither fibroblasts nor mast cells are now present.^{21 31}

Such is the observed sequence; the difficulty lies in the interpretation. The cyclic changes in the mast-cell population of loose connective tissue certainly suggest that the mast cells are concerned in some way with

Fig. 4—A part of the same tissue spread as in fig. 3. This area was dipped in water before being fixed with alcohol. There is now disruption of the mast cells; their nuclei stain darkly; and much of the metachromatic material has diffused out of the cells and become attached to adjacent connective tissue fibrils ($\times 535$).

the function of that tissue, and the clue may lie in the distribution of the metachromatic material, despite the reputed chemical differences between heparin and hyaluronic acid. The two types of metachromatism—the diffuse metachromatism of ground substance and the compact granular metachromatism of mast cells—are present alternately in the sequence of changes outlined above, suggesting that whatever their chemical relationship may be they bear an inverse functional relation to one another. The metachromatic ground substance present in the embryo would seem to be produced by the connective-tissue cells themselves; but, as cellular differentiation advances and the ground substance shrinks, the metachromatic mucopolysaccharides are seen to concentrate as granules in the tissue mast cells. Indeed, recent work suggests that the granules of mast cells are giant mitochondria^{5 54} some of whose enzymes actively participate in the concentration or synthesis of the metachromatic material whereby mast cells are generally recognised.³⁵

Speculating thus, a hundred years after the birth of Ehrlich, we come back to his original view of the mast cell as a "well fed cell" of the connective tissue. But the riddle is not yet solved and controversy will still surround this problem, as it surrounded so much of Ehrlich's own work. Recalling this latter fact, Sir Robert Muir²⁸ in writing Ehrlich's obituary notice, remarked "After all, truth needs little defence, and nothing can affect the final issue."

My thanks are due to Prof. A. C. Lendrum for his help in the preparation of this paper.

INTESTINAL OBSTRUCTION IN THE NEWBORN

REVIEW OF THIRTY-TWO CONSECUTIVE CASES

VALENTINE A. J. SWAIN N. E. FRANCE
 F.R.C.S. M.B. Wales
 SURGEON CONSULTANT PATHOLOGIST

QUEEN ELIZABETH HOSPITAL FOR CHILDREN, LONDON

UNTIL comparatively recently, operation for the relief of intestinal obstruction in the newborn held slender hope. But the outlook has been improved by wider recognition of the early symptoms, fuller knowledge of the causes, and earlier resort to surgery.

32 consecutive cases of intestinal obstruction giving rise to symptoms in the first four weeks of life are reviewed here (table I). These babies came under the surgical care of one of us (V. A. J. S.) between January, 1948, and October, 1953, and include only small-bowel and large-bowel obstruction, pyloric and anorectal obstruction having been excluded. Although the series is too small to be of any statistical significance it illustrates the pathology, diagnosis, and management of such cases.

Varieties of Obstruction

DUODENAL OBSTRUCTION : 7 CASES (TABLE II)

Intrinsic Obstruction (4 cases)

In complete occlusion of the duodenum due to atresia obstructive symptoms appeared early and persisted. Vomiting, which began as soon as feeding started, was usually copious; abdominal distension was confined to the gastric area and subsided after emptying of the stomach. In most cases straight radiographs showed gas shadows in the duodenum and stomach only (fig. 1)—an appearance which is pathognomonic. The site of obstruction was usually distal to the ampulla of Vater; in one case an atretic portion of the duodenum caused distension of the biliary passages and gall-bladder; at necropsy in another case stenosis was found to be due to a partial

septum. At operation, when the duodenum was completely obstructed, gross distension of its proximal portion could be seen; the pylorus was dilated and appeared as a thickened rim, and the transverse colon lay in its normal situation with its mesocolon stretched over the distended duodenum (fig. 2). Enlargement of the duodenum was less when the obstruction was incomplete.

In intrinsic duodenal occlusion duodenojejunostomy was carried out in 3 cases and gastrojejunostomy in 1.

Extrinsic Obstruction (3 cases)

The symptoms and signs of this type of obstruction were similar to those of the intrinsic type, and the two types could not be distinguished before operation; radiography was done after a barium meal in case 7 and showed partial obstruction to the flow of barium.

The condition found corresponded to that described by Ladd (1932) in that the duodenum was obstructed by a fibrous band running across the duodenojejunal junction (fig. 3); in addition the colon was malrotated, and the primitive enterocolic loop was free to rotate around the axis of the superior mesenteric vessels. In 2 cases volvulus had taken place, and its correction revealed the mal-developed arrangement of the gut with the jejunum to

TABLE I—DISTRIBUTION OF LESIONS IN 32 CASES OF NEONATAL INTESTINAL OBSTRUCTION

Lesion	No. of cases	Died	Recovered
<i>Duodenal :</i>			
<i>Intrinsic :</i>			
Atresia	1	1	0
Stenosis	3	1	2
Extrinsic	3	0	3
<i>Jejunum and ileum :</i>			
Atresia	4	2	2
Stenosis	1	0	1
Meconium peritonitis	2	2	0
Peritoneal adhesions	2	0	2
Meconium ileus	3	2	1
Intussusception	1	0	1
Strangulated hernia	3	0	3
Hirschsprung's disease	9	3	6
Total	32	11	21

the right and the colon to the left of the midline; in one of these cases gangrene of part of the intestine necessitated resection. The importance of dividing the obstructing fibrous bands across the distal duodenum, after untwisting the volvulus, as emphasised by Ladd, was borne out in these cases, all of which recovered.

ATRESIA AND STENOSIS OF JEJUNUM AND ILEUM : 5 CASES (TABLE III)

Stenosis of the ileum due to a partial septum was present in 1 case and atresia in 4; in the latter the obstructive symptoms and signs presented early and persisted. Radiography of the abdomen showed loops of dilated intestine contrasting with the absence of gas shadows in other parts of the film; the lower the obstruction the more numerous were the distended loops and corresponding fluid levels; these findings were useful in assessing the level of obstruction. In 2 cases of complete obstruction pale waxy trypsin-free stools were passed.

At operation the partial obstruction in case 8 (fig. 4) was relieved by a side-to-side anastomosis above and below the lesion. A year later obstruction recurred at the same site, but after excision of the obstructed segment of bowel and end-to-end anastomosis the infant finally recovered. In all 4 cases of atresia the lesions were multiple: in 1 of these exomphalos was also present, and recovery followed resection of the blind segments of the ileum and repair of the hernia; 2 infants (cases 10 and 11) were re-explored because the primary operation did not relieve the obstruction. In one of these a further site of atresia was found which had been missed by

TABLE II—DUODENAL OBSTRUCTION

Case no.	Sex	Age at onset	Age at operation	Clinical diagnosis	Anatomical findings	Type of operation	Outcome
1	F	1 day	2 days	Duodenal obstruction	Atresia of duodenum	Gastrojejunostomy	Died
2	F	1 day	9 wk.	Duodenal stenosis	Duodenal stenosis	Duodenojejunostomy	Recovered
3	M	36 hr.	8 wk.	? Pyloric stenosis	Duodenal stenosis	Duodenojejunostomy	Recovered
4	M	2 days	7 days	Duodenal obstruction	Duodenal stenosis	Duodenojejunostomy	Died
5	F	18 hr.	24 hr.	Duodenal obstruction	Extrinsic duodenal obstruction + volvulus + gangrene of jejunum	Correction of volvulus, Ladd's procedure and resection of gangrenous intestine	Recovered
6	M	3 days	7 days	High intestinal obstruction	Extrinsic duodenal obstruction, volvulus, malrotation	Untwisting of volvulus and Ladd's procedure	Recovered
7	F	3 days	4 days	Duodenal stenosis	Extrinsic duodenal obstruction, malrotation	Ladd's procedure	Recovered

omitting to test the patency of the *whole* length of the intestine by distension with saline solution; in the other (case 11) resection of 10 cm. of terminal ileum which had failed to function after the first operation was followed by clinical recovery, but two months later the baby died from gastro-enteritis. Case 9, with gross jejunal obstruction was a poor operative risk and the child died soon after a limited exploration.

MECONIUM PERITONITIS: 2 CASES (TABLE IV)

This is produced by leakage of meconium into the peritoneal cavity through a hole in the bowel—though the perforation may be closed by the ensuing reaction. In many cases it is associated with a primary obstruction somewhere in the intestinal tract, causing distension of the bowel above (fig. 5) and subsequent perforation (Boikan 1930).

Sterile meconium within the peritoneal cavity seems to act as a chemical irritant, and initiates inflammation which often leads to extensive fibrosis and diffuse calcification.

In case 14 (fig. 5), at operation at the age of 4 weeks, the intestines on the right side of the abdomen were found to be matted and twisted; after separation of the adhesions, which contained gritty particles, the terminal ileum was short-circuited because it seemed to be obstructed; the baby died seven hours after operation. At necropsy the abdominal cavity contained much blood, evidently from the surface of the freed bowel; in the distal ileum an incomplete septum reducing the lumen to 1-2 mm. in diameter was found; it was surrounded by adhesions, but no hole could be found; the pancreas was normal.

Fig. 1—Duodenal atresia, showing air in stomach and duodenum in contrast to absence of gas shadows from rest of abdomen.

The other case of meconium peritonitis (case 13) has been reported previously (Rashbass 1950). At operation the nature of the obstruction was obscured by dense adhesions in the right side of the abdomen; it was relieved by ileocolostomy. The infant survived for fifteen months, when necropsy showed duplication of the ileum, cystic fibrosis of the pancreas, and suppurative bronchopneumonia.

PERITONEAL BANDS AND ADHESIONS: 2 CASES (TABLE IV)

In these cases the obstruction giving rise to early symptoms was relieved by operation at the age of 5 and 10 weeks; in one case adhesions were found in the region of the transverse colon and the liver, while in the other they were more widespread; both babies recovered after the adventitious bands had been separated.

The origin of these bands was obscure, but omphalitis had been present previously in both babies, and one of them had had septicæmia; possibly the adhesions arose from spread of infection from the umbilicus.

MECONIUM ILEUS: 3 CASES (TABLE IV)

Meconium ileus is produced in the newborn by blockage of the bowel, usually the small

intestine, by inspissated meconium which becomes dry, tenacious, and sometimes calcified. It is associated with cystic fibrosis of the pancreas. In the present cases the signs and symptoms were those of low intestinal obstruction. In 2 of them abdominal distension was evident at birth: in 1 of these, bead-like masses of hard meconium could be felt on the right side of the abdomen; in the other a barium enema showed incomplete filling of the descending colon.

At operation in 2 cases much of the distal ileum and colon was found to contain firm pale plugs of inspissated

Fig. 2—Duodenal atresia, showing distension of obstructed duodenum, whose retrocolic portion is outlined by interrupted line; interrupted line in mesocolon indicates site of duodenal opening for duodeno-jejunal anastomosis; collapsed loops of jejunum are visible in lower part of wound.

material, above which the small intestine was grossly distended (fig. 6) with viscid dark-green meconium. The first of these 2 cases was treated by ileocolostomy, and in the second the meconium was removed through an opening in the bowel with the aid of saline lavage, as advised by Hiatt and Wilson (1948). Both infants died, the second baby developing hyperpyrexia and pulmonary hæmorrhages five days after operation. At necropsy cystic fibrosis of the pancreas was confirmed in both cases.

Fig. 3—Extrinsic duodenal obstruction due to fibrous band across duodenojejunal junction; showing mal-developed arrangement of intestines.

The third infant was treated medically with pancreatin, because trypsin was absent from the meconium and the duodenal juice; the symptoms of intestinal obstruction which occurred on the eighth day of life subsided two or three days later without operation.

INTUSSUSCEPTION : 1 CASE (TABLE V)

Obstruction occurred on the eleventh day of life and was accompanied by rectal bleeding. Abdominal colic was not conspicuous, and the intussuscepted bowel could be palpated.

IRREDUCIBLE HERNIA : 3 CASES (TABLE V)

One case presented as a feeding problem, while another had been diagnosed as epididymo-orchitis with gastro-enteritis. All 3 babies recovered.

HIRSCHSPRUNG'S DISEASE : 9 CASES (TABLE VI)

Obstruction is the result of contraction of a variable length of the sigmoid colon. In many cases it is associated with the absence of the ganglionic cells of the intramural plexuses (Bodian et al. 1949). The symptoms came on usually within forty-eight hours of birth; vomiting,

often of bile-stained fluid, occurred first and persisted, and was accompanied by increasing generalised abdominal distension and waves of visible peristalsis; there was delay in the passage of meconium, which was usually scanty. On rectal examination narrowing of the pelvic colon was detected in some cases, and sometimes faecal accumulation could be felt apparently held up by a constriction; the rectum was empty of faeces. Often the passage of a finger or a rectal tube per anum induced a bowel action, with temporary relief of obstructive symptoms. Plain radiography of the abdomen showed distension of both small and large bowel, with fluid levels in most cases. Although the diagnosis of Hirschsprung's disease was suggested radiologically in 2 cases, it was not until later in infancy that the typical segmental narrowing (fig. 7) was clearly demonstrated; with the growth of the child the narrowing portion became relatively longer, and proximal dilatation greater. In later months the distension was intermittent, and from time to time faecal accumulations could be felt in the large bowel.

Treatment aimed at relieving the intestinal obstruction until such time as the infant was fit enough to stand removal of the narrow segment by resectosigmoidectomy. Simple measures such as laxatives, suppositories, and washouts, which were used in all the cases, were temporarily successful, but in most cases an operation to overcome the obstruction was necessary: in 2 babies, at laparotomy, disimpaction of the faeces through the narrowed segment down into the rectum, followed by the passage of a tube per anum, gave relief; in 3 cases a colostomy was performed because the procedure just described was impossible or had failed to overcome the obstruction. Of the 3 infants who died, a premature baby had, in addition to other congenital anomalies, marked rectal stenosis; another baby died from peritonitis arising apparently from umbilical sepsis; and the third baby, who had string constriction of the pelvic colon, died after a plastic operation at that site.

Fig. 4—Intestinal obstruction due to ileal stenosis (case 8).

TABLE III—OBSTRUCTION OF SMALL INTESTINE

Case no.	Sex	Age at onset	Age at operation	Clinical diagnosis	Anatomical findings	Type of operation	Outcome
8	M	At birth	5 days	Intestinal obstruction	Ileal stenosis	Ileo-ileostomy (resection of obstructed ileum a year later)	Recovered
9	F	8 hr.	2 days	High intestinal obstruction	Jejunal atresia	Laparotomy	Died
10	F	At birth	26 hr.	Meconium peritonitis	Multiple ileal atresia and stenoses	Resection (3 operations)	Died
11	F	24 hr.	48 hr.	Low intestinal obstruction	Atresia of ileum	Excision of atretic ileum (2 operations)	Recovered
12	F	At birth	10 hr.	Exomphalos	Multiple atresias + exomphalos	Resection and repair of exomphalos	Recovered

TABLE IV—MECONIUM PERITONITIS, PERITONEAL ADHESIONS, AND MECONIUM ILEUS

Case no.	Sex	Age at onset	Age at operation	Clinical diagnosis	Anatomical findings	Type of operation	Outcome
13	M	At birth	20 hr.	Intestinal obstruction	Meconium peritonitis; ileal stenosis and duplication of ileum (cystic fibrosis of pancreas)	Ileocolostomy	Died at 16 mos.
14	F	At birth	4 wk.	Meconium peritonitis	Meconium peritonitis; ileal stenosis	Ileo-ileostomy after separation of adhesions	Died
15	M	10 days	15 wk.	Intestinal obstruction	Plastic peritonitis	Separation of adhesions	Recovered
16	F	At birth	5 wk.	? Pyloric stenosis	Peritoneal adhesions	Separation of adhesions	Recovered
17	F	At birth	3 days	Colonic stenosis	Meconium ileus (cystic fibrosis of pancreas)	Ileotransverse colostomy	Died
18	F	At birth	20 hr.	Meconium peritonitis	Meconium ileus	Hiatt procedure	Died
19	M	8 days	..	Meconium ileus (cystic fibrosis of pancreas)	..	No operation	Recovered

Discussion

Intestinal obstruction is characterised by vomiting, abdominal distension, and constipation, which vary with the nature, site, and degree of the obstruction.

Vomiting or regurgitation of feeds occurs in the neonatal period in a variety of disorders, such as mismanagement of feeding, stenosis or spasm of the pylorus, hiatus hernia, neonatal infections, and uræmia. Only in a small proportion of cases is vomiting due to intestinal obstruction, and it is important that in these an early diagnosis be made.

Symptoms are usually more troublesome and persistent in complete obstruction, with incomplete obstruction they often vary from day to day.

Fullness of the abdomen at birth suggests intestinal obstruction arising in utero. It may, however, be found in such conditions as foetal ascites associated with abnormalities of the urogenital tract, dilatation of the bladder due to urethral obstruction, polycystic disease affecting the kidneys or the liver, and abdominal tumours. In meconium peritonitis the abdomen is sometimes distended at birth and in addition the usual signs of obstruction are present: the adhesions may cause intestinal obstruction directly or may exaggerate the symptoms of a pre-existing obstruction. In neglected cases of imperforate anus the abdomen is soft at birth but becomes increasingly distended later. Delay or the infrequent passage of scanty motions, if accompanied by increasing abdominal distension, suggests obstruction. If the meconium is pale and putty-like, there may be a deficiency of pancreatic enzyme in the lower intestine, caused either by complete obstruction or by cystic

fibrosis of the pancreas with meconium ileus; in the latter condition the ileocaecal region is filled by a firm pale plug of inspissated material of a waxy consistence closely applied to, but not stuck to, the mucosa; the colon beyond the plug may contain some masses of this material, below which the large intestine is usually empty or contracted; the absence of trypsin from the duodenal juice, when intubation is feasible, and from the meconium will confirm the diagnosis. The obstructive symptoms and signs of meconium ileus are difficult to distinguish from ileal atresia, in which the meconium below the obstruction is of a similar nature and the presence of trypsin in the duodenum is therefore significant. The findings of amniotic squames in the meconium will exclude the presence of complete atresia (Farber 1933).

RADIOLOGICAL EXAMINATION

Plain radiography of the abdomen is invaluable. No special preparation should precede this examination, for previous stomach or bowel wash-outs may give a false impression of fluid and gas shadows. The pattern of a distended duodenum alone suggests duodenal occlusion (fig. 1), while dilatation of the small or the large bowel indicates the level of obstruction. If the caecum is seen in its normal position, malrotation of the colon can be excluded; free gas in the peritoneal cavity may result from a perforation of the bowel; intra-abdominal calcification is commonly present in meconium peritonitis, or displacement of the intestine by an encysted mass may be seen (fig. 5). A radio-opaque meal or enema is unnecessary in most cases and should be restricted to doubtful cases when the decision to operate is uncertain. The barium should be emptied through a gastric or a rectal tube after such an examination. In Hirschsprung's disease a barium enema in the first few weeks of life is of doubtful value in the diagnosis.

Fig. 6—Obstruction of terminal ileum due to inspissated meconium (case 17).

Fig. 5—Radiograph of case 14 showing (1) abdominal distension with obstructed loops of small intestine with fluid levels and (2) areas of calcification on right side.

TABLE V—INTUSSUSCEPTION AND STRANGULATED HERNIA

Case no.	Sex	Age at onset (days)	Age at operation (days)	Clinical diagnosis	Anatomical findings	Type of operation	Outcome
20	M	11	12	Intussusception	Intussusception (ileocolic)	Reduction and ileocolostomy	Recovered
21	M	12	21	Strangulated inguinal hernia	Strangulated inguinal hernia	Reduction and repair	Recovered
22	M	19	31	? Epididymo-orchitis ? hernia	Strangulated inguinal hernia	Reduction after ileo-ileostomy and orchidectomy	Recovered
23	M	21	23	Strangulated hernia	Strangulated hernia	Reduction and repair	Recovered

OPERATIVE CONSIDERATIONS

Treatment is best carried out in a neonatal centre, where suitable nursing and medical facilities are available.

Operation as soon as possible after birth offers the best results. Unfortunately neonatal obstruction often occurs in premature infants, for whom the risk of operation is serious; but it should be borne in mind that unrelieved complete obstruction will inevitably result in death. In cases of incomplete obstruction conservative treatment should not be prolonged if the response is poor or the baby's condition begins to deteriorate.

In most cases correction and maintenance of the fluid and electrolyte loss is necessary, and should be undertaken with mathematical precision (Medical Research Council 1952).

The operative treatment for most conditions causing neonatal obstruction is on well-recognised surgical lines; but there are a few in which the treatment is not so uniform:

In *duodenal obstruction* due to atresia, duodeno-jejunosomy is the procedure of choice. Extrinsic duodenal occlusion is relieved by division of the peritoneal bands across the duodenum after correcting the associated volvulus.

In *occlusion of the jejunum or ileum* resection followed by anastomosis in continuity is the ideal operation, but the disparity in the size of the bowel above and below the obstruction may present difficulty. Results are better in incomplete obstruction than in complete obstruction. As complete obstruction is often multiple, the patency of the intestine should always be tested.

In *meconium ileus* the results are poor, largely because of the viscid nature of the meconium and the inability of the lower bowel to regain its function after operation. Andersen (1949), in a review of cases of cystic fibrosis of the pancreas, reports that, after she adopted the method devised by Hiatt and Wilson (1948), 5 of her 8 cases of intestinal obstruction due to meconium blockage were successfully treated. Hiatt advocated opening the bowel

and removing the sticky meconium by saline irrigation followed by closure of the enterotomy. Gross (1953) recommended Paul-Mikulicz resection of the terminal ileum which contains the firm meconium; Nixon (1953) reported a successful case after a simple enterostomy. To avoid an external ileostomy wound, one-stage resection is preferable; but it may not be feasible, owing to the length of bowel involved or to the degree of obstruction. With all the above procedures pancreatin either locally or by mouth is necessary. Volvulus or meconium peritonitis may complicate meconium ileus; the obstructed loop, being filled with dark-green or brown meconium or faeces, may twist or perforate.

If diagnosed early some cases of meconium ileus respond to conservative measures only (case 19).

After recovery from operation, babies with cystic fibrosis of the pancreas are treated with a high-protein high-vitamin and high-calorie diet, in addition to pancreatin by mouth. Should respiratory infection supervene, chemotherapy will be necessary.

Meconium peritonitis is usually fatal, but operation holds a hope for recovery. The severity of the peritoneal reaction will depend on the extent of the extravasation of meconium; if this is large it may fill the peritoneal cavity or form an encysted collection limited by the abdominal parietes and adjacent viscera, with the intestine matted round it. If, however, the leak is small, a conglomerate mass of adherent bowel is formed round the perforation; in such cases the coils of intestine will be soiled by meconium-like material and roughened by gritty particles of calcification.

When a large collection is present, preliminary paracentesis will decompress the abdomen, and the fluid can be tested for the presence of trypsin; the abdomen is then explored, and any perforation in the bowel closed by fine suturing; in most cases the primary obstruction is difficult to find, but the anatomy may be clarified by gentle separation of the adherent intestines; the obstruction is preferably treated by resection of the affected area.

Until recently the prognosis was poor, but Low et al. (1949), Forshall et al. (1952), and Franklin and Hosford (1952) have reported successfully treated cases.

In *Hirschsprung's disease* treatment consists in relieving the obstruction and establishing regular motions by the aid of enemas and laxatives until such time as the child is old enough to stand removal of the narrowed segment by rectosigmoidectomy. We consider that it is safer to wait until 2 years of age.

In cases in which the obstruction cannot be overcome by simple measures immediate operation is necessary. In such infants, the small bowel and the large bowel are distended, with narrowing usually in the descending or pelvic colon, where an accumulation of firm meconium may be held up; by squeezing this down into the rectum

Fig. 7.—Barium enema in case 24, showing characteristic appearance of Hirschsprung's disease at age of 10 months.

TABLE VI—HIRSCHSPRUNG'S DISEASE

Case no.	Sex	Age at onset	Age at operation	Clinical diagnosis	Type of operation	Outcome
24	M	2 days	..	? Hirschsprung's disease	No operation	Recovered
25	M	1 day	6 wk.	Low intestinal obstruction	Laparotomy	Recovered
26	M	1 day	5 days	? Congenital rectal stenosis	Colostomy	Died
27	M	1 day	15 days	Stenosis of colon	Laparotomy	Died
28	F	At birth	13 days	Intestinal obstruction	Laparotomy	Recovered
29	F	At birth	5 days	Intestinal obstruction	Colostomy	Died
30	M	3 days	6 mos.	? Hirschsprung's disease	Colostomy	Recovered
31	M	1 day	2 days	? Ileal obstruction	Laparotomy (colostomy at 5 wk.)	Recovered
32	M	2 days	6 mos.	? Hirschsprung's disease	Colostomy	Recovered

and passing a rectal tube the obstruction can be relieved. Where the lower segment is too narrow for this to succeed a colostomy is made.

Even if the newborn child with this condition survives the early obstructive stages, constant supervision is required to guard against a recurrence, laxatives and regular saline washouts being given as necessary. In some cases the inconvenience and risks of frequent bowel washouts and of chronic abdominal distension justify an early colostomy; in others the disadvantages of an abdominal opening are outweighed by the establishment of regular bowel actions and diminished calibre of the colon.

Whether the late results of rectosigmoidectomy are better after the early or the delayed colostomy is uncertain. In each case the progress of the child, the certainty of the diagnosis, and the adequacy of maternal or nursing care should be considered before performing a colostomy.

After operation for these various conditions constant attention is necessary to assist the recovery of these infants. They are usually nursed in an oxygen cradle, and gastric suction is maintained. Oral feeding is withheld till flatus or motions are passed, usually within forty-eight hours; then feeding is gradually introduced, and parenteral fluids are reduced and finally stopped. The discriminate use of antibiotics will lessen the chances of postoperative infection.

PROGNOSIS

Evans (1951), Rickham (1952), Jolleys (1952), and others have drawn attention to the high mortality of intestinal obstruction in infants, which is about 75%; they all emphasised the importance of early diagnosis and the application of modern developments in the management.

Prematurity, other congenital abnormalities, and associated birth injury or infection will increase the mortality.

The symptoms vary with the degree of obstruction: complete obstruction leads to persistent symptoms and rapid deterioration in the baby's condition, and therefore operation should be rarely delayed; whereas incomplete obstruction, with its intermittent symptoms, may cause conservative measures to be unduly prolonged.

Recognition of the coexistence of volvulus and extrinsic duodenal adhesions, as emphasised by Ladd (1932), has led to an increased number of survivors. The identification by Andersen (1938) of cystic fibrosis of the pancreas as a clinical entity has led to a measure of success in the treatment of the associated meconium ileus. In cases of meconium peritonitis, which was until recently always fatal, the occasional success justifies early operation. Gastro-enteritis was a feared complication in the newborn, but should now be rare. In Hirschsprung's disease operation may be required in the neonatal period to save life, and an early diagnosis must therefore be made.

In this series of 32 infants, 11 died after operation and 21 recovered, 19 of whom had undergone operation (table 1).

It is encouraging that in recent years successfully treated cases are being more frequently reported than in the past. We may hope that advances in paediatrics and their surgical application will further improve the outlook.

Summary

32 consecutive cases of neonatal obstruction illustrate the pathology, clinical features, and treatment of duodenal obstruction, jejunal and ileal atresia and stenosis, meconium ileus, meconium peritonitis, intussusception, peritoneal bands, and Hirschsprung's disease. 21 of the infants in this series recovered.

The value of early diagnosis, radiological examination, and detailed attention to supportive measures of resuscitation is emphasised.

The elucidation of such clinical entities as fibrocystic disease of the pancreas, meconium ileus, meconium peritonitis, and Hirschsprung's disease has led to rational treatment. The present mortality of obstruction in the first weeks is more than 75%; but this high figure should be reducible.

We are much indebted to our colleagues, especially Dr. H. M. M. Mackay, Dr. R. H. Dobbs, and Dr. W. F. Young, for their kind co-operation; to Dr. C. J. Hodson and Dr. B. C. H. Ward for the radiological work; and to the nurses, the resident medical officers, and the anaesthetists for their valuable help.

Addendum

Since this article was completed, case 12 has died at the age of five months from congenital abnormality of the heart. There have been 3 further cases. 1 was a premature baby who was operated on unsuccessfully for high jejunal atresia when a week old. In the other 2 intermittent obstruction developed at the ages of 2 and 3 weeks, in each case after a generalised infection; 1 recovered after a week with conservative treatment, while the other is responding slowly to similar management after three months. In both cases the cause of the obstruction is uncertain.

SUBDURAL COLLECTION OF FLUID IN TUBERCULOUS MENINGITIS

LESLIE TURNER

M.B. Manc.

FORMERLY RESIDENT, DEPARTMENT OF NEUROSURGERY,
UNIVERSITY OF MANCHESTER

SUBDURAL collections of fluid have been known since the time of Hippocrates, or such was the opinion of Robert Whytt (1768):

"Hippocrates has enumerated in his second book 'De Morbis' the signs of 'water in the brain,' as his words have been rendered by all the translators. But *ἐπι τῷ ἐγκεφάλῳ* more properly signifies *upon* than *in* or *within* the brain, and that Hippocrates only speaks here of water lodged between the dura mater and brain can scarcely be doubted, since he proposes to evacuate it by making a perforation in the upper part of the cranium, which operation could have been of no use had the water been contained within the brain itself."

However, it is well known that the cortex may be so thin in gross hydrocephalus that it could have been mistaken for a membrane.

Nowadays subdural collections of fluid are well known, and they fall naturally into two groups: those due to intracranial bleeding, and those which occur in the presence of infection. Penfield (1923) described in a young boy a purulent subdural effusion due to a spread of infection from otitis media; Schiller et al. (1948) described a loculated subdural abscess complicating pneumococcal leptomeningitis due to frontal sinusitis; and since then other subdural empyemata spreading directly from infections of the paranasal sinuses and the middle ear have been described.

More recently attention has been drawn to subdural effusion in children with primary meningitis without any evidence of middle-ear or sinus infection. The two patients reported by Spitz et al. (1945) died of purulent meningitis, which in one case was due to a pneumococcus and in the other to *Hæmophilus influenzae*; subdural collections of fluid were found post mortem. However, this condition, as well as subdural empyema, was known long before this: Monro (1827) gives an excellent account of both, but of especial interest is his account of a boy who had an encephalomeningocele and undoubtedly died of purulent meningitis. At necropsy turbid fluid was found in the ventricles, and there were bilateral subdural effusions containing, on the right, 6 oz. of clear highly proteinous fluid, and on the left a small quantity of similar fluid. Further cases complicating purulent meningitis have been reported by McKay et al. (1950), Smith et al. (1951), Arnold (1951), Everley Jones (1952), and Guthkelch (1953). Everley Jones noted that in the previously reported cases the organism responsible for the meningitis had been *H. influenzae* in twenty cases, a pneumococcus in twelve, a paracolon bacillus in one, and *Pseudomonas aeruginosa* in one. The organism in three of his cases was a meningococcus, and he makes the point that subdural effusion had never previously been reported in meningococcal meningitis. Duperie and Dubourg (1913) reported a case in an infant of tuberculous meningitis complicated by a subdural hæmatoma; and McKay et al. (1953) have included a case of subdural effusion due to tuberculous meningitis in a table of figures, but do not refer to it in the text. I have not been able to find any other published report of a subdural collection of fluid complicating tuberculous meningitis; therefore the following case is interesting.

Case-report

A woman, aged 43, was admitted to another hospital on Sept. 15, 1952, in a stuporose condition. She could not describe her symptoms, but her husband said that she had been quite well until four months previously, when she developed, in her back, pain which extended from the cervical region to the sacrum. She had no headache and continued to work about the house and pursue her usual activities until the end of August, when she was sufficiently unwell to take to her bed. A week later she developed in her left shoulder a moderately severe aching pain which radiated down the left arm to the fingers. A few days after the onset of this pain, which persisted, occipital headache came on in such severe paroxysms that she held her hands to her head, cried out, and was completely incapacitated until the pain subsided. Three days before admission she became drowsy and confused, vomited occasionally, and developed acute retention of urine.

On examination she was confused and uncoöperative. Her temperature was normal, her blood-pressure was 170/110 mm. Hg, and she showed signs of dehydration. Her bladder was distended to 6 in. above the symphysis pubis. Examination of the central nervous system showed severe neck stiffness and a positive Kernig's sign but no localising signs. Lumbar puncture produced yellow turbid cerebrospinal fluid (c.s.f.) containing 40 leucocytes per c.mm., and 65 mg. of protein, 500 mg. of chloride, and 22 mg. of sugar per 100 ml. There was a partial block on Queckenstedt compression. Examination of the blood showed hæmoglobin 87% and 13,900 leucocytes per c.mm. (polymorphs 91%). Radiographs of the skull were normal, but a film of the chest showed diffuse miliary tuberculosis. At the hospital to which the patient was admitted she was treated with streptomycin 0.5 g. intramuscularly twice daily and 100 mg. intrathecally, and *p*-aminosalicylic acid 20 g. daily. Two days after admission it was found that the spinal subarachnoid pathway was blocked. The patient's state of consciousness had deteriorated, and she responded only to painful stimuli such as firm supra-orbital pressure and pinching of the facial skin, and it was suspected that the deterioration was due to an increase of intracranial pressure. It was therefore decided to cut burr-holes and make ventricular studies. Streptomycin could also be introduced into the ventricles if indicated. She was accordingly sent to this Unit on Sept. 18, 1952.

Operation.—On arrival at the theatre she was barely rousable, her pupils were equal but reacted poorly to light, and she had bilateral rigidity and extensor plantar responses. Under local anaesthesia bilateral frontal burr-holes were made over the coronal suture 2 cm. from the midline. The dura on the right side was tense, and on opening it there was a gush of clear fluid under pressure. About 50 ml. of this fluid was collected for examination. The cortex was separated from the dura by 1 cm., but no definite membrane was recognised. A cannula was passed into the lateral ventricle, and on the introduction of streptomycin 50 mg. more clear yellowish fluid welled up from the subdural space. The dura under the burr-hole on the left side was opened, and a second collection of fluid was released, rather less than on the right. The cortex here was also depressed.

Postoperative Course.—The patient's condition at the end of the operation was very much improved: she was more alert, could answer questions, and said that she had no headache. She maintained this improvement for four days, but her condition then deteriorated: she developed increasing abdominal tympanites and vomiting, and died on Sept. 24, six days after the effusions had been drained.

Necropsy Findings.—Diffuse miliary tuberculosis of the lungs was confirmed, and scattered tubercles were found in the kidneys. The stomach and intestines were atonic and distended. The brain showed flattening of the cortex over the front of the hemispheres, and some reddening of the dura at the site of operation, but no further collection of fluid was found. There were gelatinous adhesions over the base of the brain, but the striking finding was a thick jelly-like exudate covering the spinal cord from the upper cervical segments to the region of the conus medullaris; this was more organised and clearly of longest standing in the cervical region.

The subdural fluid collected at operation had clotted on arrival at the laboratory, and it must therefore have contained much protein. Attempts to culture tubercle bacilli from the clot failed.

The ventricular fluid was slightly turbid, there was no coagulum; it contained 3 lymphocytes and 183 red blood-cells per c.mm., and 28 mg. of protein and 68 mg. of sugar per 100 ml. The chloride content was not estimated. There was no excess globulin, and attempts to culture tubercle bacilli failed.

Discussion

INTERPRETATION

This patient evidently had miliary tuberculosis, and her central nervous system became involved, beginning with spread to the cervical cord—a rare mode of onset, but important to recognise if such cases are to be diagnosed early enough for treatment to be successful. The history of her illness indicated that some weeks elapsed before the onset of severe headache heralded intracranial extension of the spinal infection. This was followed by rapid deterioration in her level of consciousness which was, no doubt, due to the development of the subdural effusions. As often happens, this patient had widespread foci of active infection in places other than the central nervous system, and death might easily have resulted ultimately from one or other of these.

MANAGEMENT OF TUBERCULOUS MENINGITIS

Since the introduction of streptomycin the management of tuberculous meningitis has undergone very critical examination from time to time, and in recent years it has become evident that surgery has an important but limited part to play, not in a desperate attempt to rescue patients with advanced meningeal infection which, because of inflammatory exudate, is already beyond the reach of streptomycin, but in the treatment of the few cases which, after cure or control of the initial infection, develop a tuberculoma, a tuberculous abscess, or a block somewhere in the cerebrospinal subarachnoid pathways, with resulting hydrocephalus.

In the active stage of tuberculosis attempts to prevent or short-circuit the obstructing granulations in the basal and ambient cisterns have proved disappointing, for in most cases the deterioration has been due not to obstruc-

tion but to neuronal damage following thrombosis of vessels surrounded by granulations.

There are, however, very good reasons for making exploratory burr-holes in any case of tuberculous meningitis when the level of consciousness deteriorates fairly suddenly and evidence of an acute rise of pressure is found.

Cairns (1951) described two cases in which the intracranial pressure rose suddenly. One of these patients died and was found at necropsy to have a tuberculous abscess in the left parietal lobe. The other, a boy aged 3 years, developed signs of an acute rise of intracranial pressure and was found to have localised hydrocephalus of the temporal horn of the right lateral ventricle; this was relieved by operation and he recovered.

A third case which illustrates the importance of burr-holes and ventriculography was recently transferred to this Unit from another hospital. This patient, a married woman aged 26, had been treated for about three months for tuberculous meningitis and had made a good recovery, when she began to have severe intermittent headache suggesting attacks of hydrocephalus. Ventriculography revealed a space-occupying lesion in the right cerebellar hemisphere, and at operation a tuberculous abscess was successfully removed.

In the present case the subdural collection of fluid rapidly produced a severe impairment of consciousness. This was immediately relieved by drainage; so possibly more cases of subdural effusion await discovery in patients with tuberculous meningitis whose symptoms suggest raised intracranial pressure of acute onset, and drainage may be beneficial and even life-saving.

ÆTIOLOGY OF SUBDURAL COLLECTIONS OF FLUID

The ætiology of subdural hæmatoma and hydroma resulting from trauma is well understood; so it is sufficient here to point out that in both conditions the arachnoid may be torn (Quincke 1906, Hardman 1939). The cause of subdural collections of fluid associated with meningitis is not so clear, but they are probably in most cases also due to rupture of the arachnoid membrane. Although Spitz et al. (1945) have been widely cited as believing that these effusions are due to escape of blood from a thrombosed subdural vein, they suggested five different possible mechanisms.

(1) *Direct Extension through a Necrotic Arachnoid Membrane, either at the Arachnoid Villi or over the Hemispheres.*—This is an obvious mechanism of spread of infection to the subdural space in cases where the causal organism has strong cytolytic power, but this has been a necropsy finding in cases of virulent infection (especially by *H. influenzae*) and is unlikely to explain the effusions found in mild cases.

(2) *Simple Transudate through Damaged Arachnoid.*—This theory has received support from Smith et al. (1951), Everley Jones (1952), Gitlin (1952), Guthkelch (1953) (for effusions containing little protein), and McKay et al. (1953). It is natural to believe that a membrane such as the arachnoid could permit transudation when it is inflamed, just as do the pleura and peritoneum. It is, however, very unlikely that simple transudation can be the sole cause, because all cases of meningitis are accompanied by meningeal inflammation, yet few of them develop subdural effusions of sufficient size to cause symptoms.

(3) *Escape of Blood from Thrombosed Vein.*—Aseptic thrombosis of cerebral veins and sinuses is known to be associated with intracerebral, subarachnoid, and subdural hæmorrhage (Russell 1949, Barnett and Hyland 1953); but in such cases the bleeding has clearly taken place not from thrombosed subdural veins but from engorged capillaries in areas of infarction. Guthkelch (1953) suggested that this might be the mechanism in effusions containing much protein; but the protein content of effusions, like that of c.s.f., varies with the infecting organism and the chronicity of the disease.

(4) *Involvement of Subdural Space secondary to Thrombosis of Venous Sinus.*—It is most unlikely that this is the cause of subdural collections, since the incidence of such effusions has not lessened with the advent and use of antibiotics, which are very effective in preventing sinus thrombosis; and the fact that sinus thrombosis and effusions may be present together is not proof that the one is the cause of the other.

(5) *Simultaneous Involvement of both Arachnoid and Dura by Blood-borne Infection.*—Although Spitz et al. (1945) had no evidence from their material that this ever happened, they mention this theory, which may be very important. Consideration of the portals of entry of meningitis leaves little doubt that focal embolic sepsis in the bone, the emissary veins, or the cortex may be the start of meningitis, brain abscess, and subdural infection (Johnson 1953).

Rupture of Arachnoid Membrane.—I suggest an alternative mechanism—simple rupture of the arachnoid membrane due to raised subarachnoid pressure.

In meningitis, probably because of arachnoidal inflammation and impaired absorption of c.s.f., the subarachnoid pressure is raised. An inflammatory exudate from the vascular pia-arachnoid passes into the subarachnoid space and, together with œdema in the underlying cortex, produces obstructions at various places in the cerebrospinal subarachnoid pathways.

The arachnoid mater is normally thinner over the hemispheres than at the base and, unlike the pia mater, bridges over the sulci, except where it dips into them a little on the walls of emerging veins. The subarachnoid space is shallow over the summits of the gyri but deeper over the sulci, and the pia and arachnoid are connected by fine connective-tissue trabeculæ. These trabeculæ are not normally under tension.

With exudate adding to the volume of fluid in the ventricles and subarachnoid space, and at the same time seriously diminishing absorption at the villi, the intracranial tension rises, the brain becomes œdematous, and the gyri become wider, partially obliterating the sulci and squeezing the fluid out of them. This fluid, which may be loculated by adhesive arachnoiditis, distends the subarachnoid space and tears the delicate arachnoid, allowing a spurt of c.s.f. and exudate to reach the subdural space. Tight trabeculæ may determine the point of rupture.

Once in the subdural space, such a collection would tend to spread, and the protein in it might form a membrane which would become vascularised by new capillaries from the dura. Moreover, once the effusion had formed, the obstruction to the absorptive area would be increased and a pressure gradient would exist from the subarachnoid space, deep to the thin inner membrane of the effusion, to the arachnoid villi adjacent to the sinus. This would probably increase the effusion, aided perhaps by osmosis and a leakage of red cells from the membrane as its young vessels were stretched.

That effusions are a result of a tear in the arachnoid is supported by Cairns et al. (1946), who described a trial of intrathecal penicillin in a case of suppurative meningitis. Penicillin was administered by lumbar puncture, and twelve hours later it had disappeared from the c.s.f.; so these workers introduced penicillin directly into the ventricles. On making frontal burr-holes they found a large subdural collection of yellow fluid containing 0.5 units of penicillin per ml., while the ventricular fluid contained 1 unit per ml. Some of this penicillin must clearly have passed through a hole in the arachnoid membrane. It did not simply diffuse, for after the injection of 8000 units of penicillin into the subdural space at the site of the effusion none appeared in the c.s.f., indicating that either the hole had closed or it was a valve-like one-way opening.

Everley Jones (1952), by injecting indigo carmine into an effusion, showed that effusions do not remain in contact with the subarachnoid space. Further evidence that rupture of the arachnoid may follow increased subarachnoid pressure is to be found in descriptions by Dandy (1944), Bassett and Lemmen (1952), and Logue (1951) of subdural hæmatoma complicating subarachnoid hæmorrhage.

The rarity of subdural collections in tuberculous meningitis may possibly be explained by the fact that

sudden rises in subarachnoid pressure with distension of the subarachnoid space are rare in this disease.

Summary

A fatal case of subdural collection of fluid complicating tuberculous meningitis is described.

It is important to make burr-holes in cases where the level of consciousness suddenly deteriorates.

A tear in the arachnoid is probably the important factor in the aetiology of subdural collections of fluid.

I wish to thank Dr. G. H. H. Benham, who referred the case, for the use of his records and the necropsy report; Sir Geoffrey Jefferson, F.R.S., for drawing my attention to Monro's book; and Mr. R. T. Johnson, O.B.E., F.R.C.S., for permission to publish and for kindly advice and criticism.

POST-TRANSFUSION SURVIVAL OF RED CELLS STORED AT -20°C

RED blood-cells mixed with glycerol can be frozen to -79°C and thawed without hæmolysis (Smith 1950). If the cells are freed from glycerol and transfused they survive normally in the recipient's circulation (Sloviter 1951, Mollison and Sloviter 1951). Red cells suspended in citrate-plasma and mixed with an equal volume of 30% (*w/v*) glycerol in 0.9% saline solution (i.e., final glycerol concentration 15% *w/v*) undergo progressive lysis if stored at -79°C , with the result that after six months only 60% of them may be recovered. However, these red cells have an almost unimpaired survival in vivo (Mollison et al. 1952). Red cells stored in the same mixture at -20°C undergo even more rapid lysis; but the cells recovered after three months' storage may survive well in vivo (Mollison et al. 1952). This last finding suggested that at -20°C chemical changes in red cells might be virtually arrested and that, if physical damage could be prevented, prolonged storage at -20°C could be achieved. -20°C is a temperature that can be maintained very easily—for example, in an ordinary ice-cream cabinet. It would therefore be a great advantage

if prolonged preservation of red cells were possible at this temperature rather than at some lower temperature.

Chaplin and Mollison (1953) reported that, if red cells were mixed with citrate-glycerol rather than with saline-glycerol, and if the final concentration of glycerol were raised from 15% (*w/v*) to 30% (*w/v*), the rate of hæmolysis during storage at -20°C was enormously reduced. After three months' storage 98% of the red cells were intact. In view of the previous demonstration that red cells stored at -20°C for three months survived normally, it seemed likely that red cells stored in the new solution would survive well; but these workers pointed out that measurements of survival in vivo would have to be made before the usefulness of the method of storage for transfusion was established.

We report here mainly the post-transfusion survival of red cells stored in different glycerol mixtures at -20°C . Red cells stored in the citrate-glycerol mixture originally described do not survive well, but in slightly modified mixtures survival remains very good until the period of storage exceeds three months. Thereafter viability is lost progressively with time. Red cells stored at -20°C slowly consume dextrose, and their loss of viability is probably due to the fact that chemical changes are not completely arrested at -20°C .

Methods

STORAGE TEMPERATURES

A temperature of about -20°C was maintained in a 'Prestcold' refrigerator cabinet, model CC 82. Bottles of blood for transfusion were kept in the lower compartment, in which the temperature ranged from -21°C to -24°C . Smaller samples of blood were kept in the upper compartment of the refrigerator, in which the temperature ranged from -18°C to -20°C . For convenience storage in the range from -18°C to -24°C is referred to here as " -20°C ."

A few experiments made at other temperatures are included here. These temperatures were maintained as follows:

For storage at -79°C a special insulated box was used containing a large tank in which solid carbon dioxide was placed as often as necessary, and a smaller tank containing alcohol in which the bottles or tubes of blood were kept. Solid carbon dioxide was added to the alcohol bath two or three times a week; this kept the temperature in the bath between -75°C and -79°C . Occasionally the temperature in the bath rose to -70°C . A temperature of -10°C was maintained in a cold-room, and $+4^{\circ}\text{C}$ in an ordinary domestic refrigerator.

BLOOD-GLYCEROL MIXTURES

Red cells of group O type M or of group A type N were obtained from blood collected at routine bleeding sessions of the North London Transfusion Centre. This blood was taken into A.C.D. solution (disodium citrate 2 g., dextrose 3 g., water 120 ml., mixed with 420 ml. of blood) and stored for either twenty-four or forty-eight hours at $+4^{\circ}\text{C}$. The red cells were next packed by centrifugation, and almost all the supernatant plasma-citrate solution was removed. The bottles usually contained about 230 ml. of packed red-cell suspension; it was estimated that about 20 ml. of this volume consisted of plasma citrate either trapped among the red cells or lying on the surface of the suspension. To this packed-cell suspension was added an equal volume (about 230 ml.) of one of the following mixtures:

Solution I (trisodium citrate/glycerol).—This mixture was the one described by Chaplin and Mollison (1953). 40 volumes of glycerol was added to 60 volumes of 5% trisodium citrate (the pH of this solution is 7.7). On the assumption that glycerol diffuses freely into 60% of the red-cell volume, the final concentration of glycerol after mixture with the packed cells is 30% (*w/v*), or 3.3 M; citrate is assumed not to penetrate the red cells, and its final concentration in this

* Senior assistant surgeon, U.S. Public Health Service (Res.).

mixture is therefore 0.1 M. In two additional experiments described below this solution was modified to give a final glycerol concentration of 20% and 40%.

Solution II (tripotassium citrate/glycerol).—40 volumes of glycerol was added to 60 volumes of 5.5% tripotassium citrate (final concentration of citrate about 0.1 M).

Solution III (buffered tripotassium citrate/glycerol).—40 volumes of glycerol was added to 60 volumes of a solution containing tripotassium citrate 3.25%, dipotassium hydrogen phosphate 0.6%, and potassium dihydrogen phosphate 0.47% to give the following final concentrations: citrate 0.06 M, each phosphate 0.02 M. The pH of this solution is 6.9.

Solution IV (plasma citrate/glycerol).—150 ml. of supernatant plasma-citrate was saved after centrifuging the blood and mixed with 90 ml. of glycerol and 9 ml. of 30% trisodium citrate (solution rva) or with 20 ml. of 30% citrate (solution rvb). The concentration of citrate is about 0.05 M (rva) or 0.09 M (rvb), and the pH of the solution is 7.4. The final concentration of glycerol after mixture with red cells is 3.3 M.

A few investigations were made with two other solutions: (1) in one solution "dextran-citrate-glycerol," dextran (Bengers) was substituted for plasma-citrate in mixture rva (the final concentration in this mixture was 0.03 M); and (2) in the other solution "lactate-glycerol (with added calcium)," 1 volume of the following solution was added to 1 volume of packed red cells from heparinised blood: glycerol 40 volumes mixed with 60 volumes of sodium-lactate solution to give a final concentration of 0.16 M; calcium chloride was added to give a final concentration of 0.005 M.

In each case the glycerol solution was added slowly to the packed red cells with constant agitation of the mixture. After about thirty minutes the bottles were placed in the -20°C refrigerator.

In some further experiments blood was kept solely for tests *in vitro*; in these cases heparinised blood was used. Packed red cells were obtained by centrifugation and mixed with one of the four solutions already described or with various modifications described below in the results.

REMOVAL OF GLYCEROL FROM RED CELLS AFTER STORAGE

The blood was thawed by placing the container in water at 40°C and agitating it until no ice was visible. The mixture was then centrifuged and the supernatant fluid replaced by a solution containing 16% glycerol in 3% trisodium citrate. The solution and red cells were well mixed and then immediately centrifuged again. The supernatant fluid was now replaced with 8% glycerol in 3% citrate and then successively with 4% glycerol in 3% citrate, 2% glycerol in 3% citrate, and saline solution. Either two or three washes in saline solution were used. The red cells were finally suspended in an approximately equal volume of saline solution.

In a few cases the glycerol content of the final supernatant solution was estimated by oxidation with periodic acid and determination of the formaldehyde formed (Karnovsky and Brumm 1954, MacFadyen 1945).

ESTIMATION OF HÆMOLYSIS IN VITRO

The percentage hæmolysis in a sample was calculated as follows:

The hæmoglobin concentration sample of the supernatant fluid (Hb_s) and of the whole (Hb_w) were determined in a photo-electric colorimeter with an Ilford 625 filter. Percentage hæmolysis was expressed as

$$\text{Hb}_s \times \frac{100 - \text{P.C.V.}}{100} \times 100,$$

P.C.V. being the packed-cell volume of the whole sample.

In most cases appreciable additional hæmolysis occurred during the washing of the red cells to remove glycerol. The over-all recovery of red cells was estimated as the total hæmoglobin content of the sample after washing, divided by the total hæmoglobin content of the sample immediately after thawing.

MEASUREMENT OF SURVIVAL IN VIVO

All the recipients were of group A type M, and most of them were women whose anæmia was related to pregnancy or to parturition. To ensure an adequate rise in hæmoglobin concentration, fresh blood of group AM was often transfused in addition to the stored red cells (of group OM and AN).

Transfused red cells in the recipient's blood were counted after differential agglutination by Dacie and Mollison's (1943) modification of Ashby's method. Counts were made twenty-four and forty-eight hours after transfusion and after a week; in most cases further counts were made at intervals until most of the transfused cells had been eliminated.

The sera used were either anti-M powdered globulin obtained from Lederle Laboratories or anti-A produced in rabbits by the method of Morgan (1943); with the anti-M serum pre-transfusion ("blank") counts were 5000 or less per c.mm. in each of 19 cases, and with the anti-A serum 10,000 or less per c.mm. in 15 out of 19 cases; in the remaining 4 cases the blanks were between 12,000 and 25,000 per c.mm.

The concentration of transfused cells expected on the day after transfusion, if 100% had survived, was calculated from the formula:

$$\frac{\text{number of red cells transfused}}{\text{total red-cell volume}} \times \text{P.C.V.}$$

(No allowance was made for the small fraction of red cells—about 0.85%—which would be expected to disappear in a day.)

The number of red cells transfused was estimated from the volume and red-cell count of the transfused red-cell suspension; the volume was calculated by weighing the bottle with its contents before and after transfusion and determining the specific gravity of the cell suspension; the red-cell count of a well-mixed sample was determined by counting not less than 4000 red cells.

Red-cell volume was determined, on the day after transfusion, by a modification (Chaplin 1954) of the ^{32}P method of Reeve and Veall (1949).

Packed-cell volume was determined in Wintrobe hæmatocrit tubes spun for fifty-five minutes at 3000 r.p.m. in a centrifuge of radius 15 cm.; correction for trapped plasma was made by the method of Chaplin and Mollison (1952).

The packed-cell volume of a sample taken forty-eight hours after transfusion was often a little higher than that of a sample taken at twenty-four hours. Accordingly, in estimating the percentage survival at forty-eight hours and subsequently, the predicted 100% survival, calculated as described above, was corrected by the factor:

$$\frac{\text{P.C.V. two days after transfusion}}{\text{P.C.V. one day after transfusion.}}$$

No corrections were made for changes in P.C.V. after forty-eight hours since many of the recipients were anæmic women in whom the rise in P.C.V. during the period of the observations was due partly to an increase in red-cell volume.

CHANGES IN CELL VOLUME

Mean cell volume (M.C.V.) was determined in the usual way from packed-cell volume and red-cell count (4000 cells counted); it was arbitrarily assumed that initially M.C.V. was 90 μ in all cases, and observed values were expressed as percentages of this figure. A second estimate of cell swelling or shrinking was obtained by measuring mean corpuscular hæmoglobin concentration (M.C.H.C.) from the hæmoglobin concentration and packed-cell volume of the sample; it was assumed that the M.C.H.C. was initially 34%, and departure of observed values from this figure was taken to indicate alteration in cell volume. In 50 cases in which changes in cell volume were estimated

TABLE I—POST-TRANSFUSION SURVIVAL OF RED CELLS STORED ABOUT TWELVE WEEKS IN VARIOUS SOLUTIONS AT -20°C

Solution	No. of cases	Average period of storage (weeks)	Percentage survival after transfusion (days)		
			1	2	7
I. Trisodium citrate/glycerol ..	7	12.6	56	48	44
II. Tripotassium citrate/glycerol ..	5	12.6	64	64	59
III. Buffered tripotassium citrate/glycerol ..	3	13.3	84	80	73
IV. A.C.D. plasma-citrate-glycerol ..	6	12.2	92	89	84

by these two methods the standard error of the difference between the two estimates, expressed as a coefficient of variation, was 8%.

In table II the figure given for cell volume (expressed as percentage of normal) is the mean of estimates obtained by the two methods.

INTRACELLULAR SODIUM AND POTASSIUM CONCENTRATIONS

Sodium and potassium concentrations were determined with the flame photometer (Domingo and Klyne 1949) by the method of Selwyn and Dacie (1954). The results were corrected by the factor

$$\frac{\text{M.C.V. after storage}}{\text{M.C.V. before storage}}$$

to allow for changes in cell volume; M.C.V. before storage was assumed to be 90 c.μ.

OSMOTIC FRAGILITY

The method of Parpart et al. (1947), as modified by Crawford et al. (1953), was used.

ESTIMATION OF DEXTROSE

Experiments were made to compare the rate of dextrose consumption by red cells at different temperatures. Dextrose was estimated by the method described by King (1951), except that the blood was pipetted into distilled water instead of isotonic sodium-sulphate solution; and thus the estimate of dextrose concentration includes some of the reducing substances in red cells. In preliminary tests it was shown that the presence of glycerol did not interfere with the estimations.

TABLE II—INTRACELLULAR CATION CONCENTRATION, CELL VOLUME, AND OSMOTIC FRAGILITY IN RED CELLS STORED FOR ABOUT THREE MONTHS AT -20°C IN FIVE CITRATE-GLYCEROL MIXTURES

Solution	No. of samples	Period of storage (weeks)	Mean survival in vivo at 24 hours (%)	Intracellular cation concentration (m.eq. per litre)			Cell volume (% of normal)	Median osmotic fragility (% NaCl)
				Na	K	Total		
I. Trisodium citrate/glycerol ..	3	11-13	63	49	16	65	76	0.264
II. Tripotassium citrate/glycerol	3	10-15	64	14	45	59	74	0.276
III. Buffered tripotassium citrate/glycerol ..	2	14-15	84	19	68	87	88	0.350
IVa. A.C.D. plasma-citrate-glycerol	2	11-12	92	65	31	96	86	..
IVb. A.C.D. plasma-citrate-glycerol	1	14	78	65	20	85	88	0.350
Normal values	15	100	115	100	0.424

The intracellular cation concentrations have been corrected for changes in cell volume. The median osmotic fragility is in some cases derived from single samples only.

Red cells from heparinised blood were mixed with trisodium-citrate glycerol (solution I), and then sufficient dextrose was added to bring the final concentration to 90-140 mg. per 100 ml. Aliquots of the blood were then stored at each of the following temperatures: -79°C, -20°C, -10°C, and +4°C. At intervals a sample stored at each of these temperatures was thawed and its dextrose concentration estimated.

RED-CELL ANTIGENS

Blood from 7 donors was stored at -20°C in citrate-glycerol mixtures for a year. In most cases the blood mixtures were stored in 2-3 ml. amounts in small tubes. The ability of the red-cell antigens to react with standard antisera was tested at intervals during the year. After three months' storage samples were tested with only a few antisera (anti-A, anti-M, anti-N, anti-S, anti-P, and anti-D); after five months' and twelve months' storage at least two samples were tested with anti-A, anti-M, anti-N, anti-S, anti-D, anti-C, anti-c, anti-P, anti-Le^a, anti-Le^b, anti-Lu, and anti-Fy^a; only one sample was tested with anti-B, anti-E, and anti-K.

On the day of the test a fresh sample of blood was taken from the same donor, and 1% cell suspensions of both

Fig. 1—Post-transfusion survival of red cells stored at -20°C in trisodium citrate/glycerol (solution I). In this figure and in figs. 2 and 3 the numbers at the end of each curve indicate the period of storage in weeks.

stored and fresh cells were prepared. Serial dilutions of each antiserum were made in bulk, and then a small volume of each was mixed with an equal volume of the cell suspension to be tested. The reactions of the frozen cells were compared with those of the fresh cells on the same slide, both macroscopically and microscopically.

Results

RATE OF SPONTANEOUS HÆMOLYSIS IN VITRO

In experiments in which packed red cells from heparinised blood were mixed with citrate-glycerol solution and stored at -20°C the effect of varying the glycerol concentration and the citrate concentration was assessed.

When the final concentration of glycerol was 30% (w/v), the average percentage lysis after a year's storage was about 15%. Increasing the concentration of glycerol to 40% (w/v) produced no appreciable decrease in lysis. When the concentration of glycerol was lowered to 20% (w/v), there was an increase in lysis—namely, 6% lysis after three months' and 50% lysis after six months' storage.

After a year's storage no consistent differences were observed between mixtures containing concentrations of trisodium citrate varying from 2.6 to 3.2%. However, when part of the sodium citrate was replaced by citric acid, the rate of lysis was slightly diminished—e.g., in one experiment the average hæmolysis after a year in

Fig. 2—Post-transfusion survival of red cells stored at -20°C in buffered tripotassium citrate/glycerol (solution III).

8 mixtures containing 2.9-2.3% trisodium citrate and 0.1-0.5% citric acid was 5.3% (range 3.7-6.3%) compared with 8.3% (range 7.9-8.6%) in 3 mixtures containing trisodium citrate alone. The substitution of 3% potassium citrate for 3% sodium citrate did not affect the rate of hæmolysis.

When the red cells were washed three times in saline solution before being mixed with trisodium-citrate glycerol and stored they did not hæmolyse more rapidly than unwashed cells in the same solution.

These results were all obtained with red cells from heparinised blood stored in small test-tubes. Additional information about the rate of spontaneous hæmolysis was obtained from estimations made on the bottles used for transfusion. Red cells stored in solution III for eleven to fifteen weeks showed less than 2.5% hæmolysis. Red cells stored in solution IV for up to nineteen weeks showed less than 3% hæmolysis; after from twenty-four to thirty-one weeks there was between 3% and 7% hæmolysis.

Red cells stored in dextran-citrate-plasma for sixteen weeks showed 7% hæmolysis; heparinised red cells stored for twelve weeks in the lactate-glycerol solution showed 44% hæmolysis. However, experiments in vitro undertaken subsequently showed that in a solution of sodium lactate and glycerol buffered with phosphates hæmolysis took place only slowly.

The figures for hæmolysis given so far refer to the mixtures immediately after thawing. During the "recovery" of the cells—i.e., the washing, first in decreasing concentrations of glycerol and subsequently in saline solution—further hæmolysis took place, but

Fig. 3—Post-transfusion survival of red cells stored at -20°C in plasma-citrate-glycerol (solution IV).

usually only about 5% in red cells stored in solutions I-IV. As mentioned above, the percentage recovery expresses the proportion of red cells actually available for transfusion compared with the number originally frozen. In solutions I-IV recoveries were usually about 90%; in solution IV recovery was estimated on 9 bottles, stored for eleven to thirty-one weeks, and the average was 91.5%.

In the unbuffered lactate-glycerol solution there was gross hæmolysis on thawing, followed by considerable further lysis on washing; thus, in the bottle stored for twelve weeks in which there was 44% hæmolysis on thawing, the final recovery was only 31%.

SURVIVAL OF RED CELLS IN VIVO

Solution I (trisodium citrate/glycerol).—14 transfusions of blood stored for two days to twenty-one weeks were given; in 10 the red cells had been stored with 30% glycerol, and the survival of 7 of these is plotted in fig. 1. Note that viability diminishes rapidly during storage, with the result that after only three weeks at -20°C the percentage survival twenty-four hours after transfusion has fallen to 70%.

The twenty-four-hour survival of all 14 cases is shown in fig. 4. Note that the post-transfusion survival of red cells stored in 20% glycerol and 40% glycerol appears to be the same as that of the cells stored in 30% glycerol.

For comparison with results obtained with other solutions the average survival in 7 cases in which the period of storage was eleven to fourteen weeks is given in table I.

Solution II (tripotassium citrate/glycerol).—5 transfusions were given; the period of storage ranged from ten to fifteen weeks.

The average post-transfusion survival is shown in table I for comparison with the survival of red cells stored for a similar period in the other solutions.

Red cells stored in solution II had a slightly higher average survival than red cells stored in solution I, but the difference was not significant.

Solution III (buffered tripotassium citrate/glycerol).—4 transfusions were given; the period of storage ranged from eleven to eighteen weeks. The survival of the red cells is illustrated in fig. 2, and the twenty-four-hour survival is also shown in fig. 5. The average survival of 3 cases in which the period of storage ranged from eleven to fifteen weeks is given in table I. It is evident that viability is far better maintained in this solution than in solutions I and II.

Solution IV (plasma-citrate-glycerol).—11 transfusions were given; 9 of red cells stored in solution IVa and 2 in solution IVb. The period of storage ranged from eleven to thirty-one weeks. There was little difference between the survival of the red cells stored in solution IVb and those stored in solution IVa, and the results are therefore

Fig. 4—Percentage survival twenty-four hours after transfusion of red cells stored at -20°C for various periods in trisodium citrate/glycerol (solution I). Crosses represent cases stored in standard solution, final glycerol concentration 30%; two circles are cases in which the glycerol concentration was 20%; and two solid dots cases in which glycerol concentration was 40%.

considered together. In 7 cases the survival of the red cells was followed for more than a week after transfusion, and the results in these 7 cases are illustrated in fig. 3. The percentage survival of all 11 cases at twenty-four

Fig. 5—Percentage survival twenty-four hours after transfusion of red cells stored at -20°C for various periods in plasma-citrate glycerol (solution IV), marked by solid dots, and in buffered potassium citrate/glycerol (solution III), marked by circles.

twelve or fourteen weeks' storage but thereafter diminished more rapidly. As fig. 3 shows, red cells stored for twelve to fourteen weeks often had a post-transfusion survival scarcely distinguishable from that of fresh red cells.

Other solutions.—A single transfusion of red cells stored in dextran-citrate-glycerol for sixteen weeks was given. The percentage survival twenty-four hours after transfusion was 70%.

3 transfusions of blood stored in lactate-glycerol solution (with added calcium) were given. In the first 2 cases, in which the periods of storage were nine and eleven weeks, the survival twenty-four hours after transfusion was about 80%. In the 3rd case, in which the red cells were stored for twelve weeks, survival was only 25%. No reason for this gross discrepancy was found. It did not seem worth while making further experiments with this solution in view of the rapid rate of spontaneous haemolysis *in vitro* (see above).

EFFECT OF WASHING ON SURVIVAL OF RED CELLS

Fresh Red Cells Washed in Saline Solution

2 transfusions were given of fresh red cells washed seven times in 0.85% unbuffered saline solution. In the

Fig. 6—Estimates of dextrose concentration in red cells mixed with citrate/glycerol (solution I) after various periods of storage at $+4^{\circ}\text{C}$, -10°C , -20°C , and -79°C .

1st case the red cells were from blood which had been taken into A.C.D. solution and kept ten hours at $+4^{\circ}\text{C}$; in the 2nd case the blood was taken into heparin immediately before being washed. At twenty-four hours the survival figures were 100% and 101% respectively; at forty-eight hours 100% and 95%; and at twenty-eight days 79% and 69%. It was concluded that seven washes in physiological saline solution did not affect the viability of fresh red cells.

Stored Red Cells Washed in Citrate Solutions of Different pH

A second experiment was made to discover whether the survival of stored red cells was affected by the pH and dextrose content of the solution in which they were washed. Two bottles of stored red cells were mixed, and the red cells were then put in two separate bottles. The red cells in one bottle were washed in the ordinary solutions (a) of glycerol in 3% trisodium citrate (pH 7.7, dextrose nil). Those in the second bottle were washed in solutions (b) to which one part in twenty of A.C.D. solution was added to give a pH of 6.9 and a dextrose content of 0.125%. In the actual experiment

Fig. 7—Percentage survival twenty-four hours after transfusion of red cells stored at $+4^{\circ}\text{C}$ for various periods in trisodium citrate and in A.C.D. solution. Crosses are from data published by Ross et al. (1947) and solid dots from data assembled by Mollison (1951).

two bottles of group-AN red cells stored for sixteen months at -79°C were pooled and then divided into two lots and washed differently as described; two bottles of group-OM red cells stored for six months at -20°C were treated in the same way. The red cells were then transfused as follows: one patient received group-AN cells washed in solutions (a) and group-OM cells washed in solutions (b); the second patient received group-AN cells washed in solutions (b) and group-OM cells washed in solutions (a). This plan was adopted to eliminate systematic errors due to differences between recipients. The mean percentage survival of the cells washed in solutions (a) was the same as that of the cells washed in solutions (b). It was concluded that there was no advantage in adjusting the pH of the wash solutions from 7.7 to 6.9 or in adding dextrose to them in a final concentration of 0.125%.

GLYCEROL CONCENTRATION IN WASHED RED-CELL SUSPENSION

In 10 cases a sample of the red-cell suspension used for transfusion was centrifuged and the glycerol concentration of the supernatant fluid determined. Preliminary observations had shown that the glycerol concentration of the whole red-cell suspension was very close to that of its supernatant fluid. The glycerol concentration in the supernatant fluid was found to vary between 0.01 and 0.1%, the higher figures being found in cases in which the red cells had received only two washes in saline solution (following the washes in decreasing concentrations of glycerol, as described above), and the

lower figures in cases in which three washes in saline solution had been given. No correlation was observed between glycerol concentration and red-cell survival.

CELL VOLUME, INTRACELLULAR CATION CONCENTRATION, AND OSMOTIC FRAGILITY

Red cells mixed with glycerol-citrate solutions show some initial swelling, amounting to about 20% in solution I. This swelling is maximal within an hour; thereafter the cells begin to shrink, but at the end of twenty-four hours they are still about 10% above their original volume. During storage at -20°C there is progressive shrinkage, which is associated with a loss of total base and a decrease in osmotic fragility. By the end of about a month red cells mixed with solution I have shrunk to about 80% of their original volume and have lost about 50 m.eq. of base per litre of cells. Little further change takes place during a further five months' storage. Some examples of the changes observed in red cells stored for three months in solutions I-IV are given in table II.

Measurements of sodium transport on red cells stored three months in solution I were kindly made by Prof. M. Maizels and Dr. E. J. Harris. It was found that the sodium transport was substantially normal but that cell permeability was increased. In a second estimation cells stored five months in solution I were examined; these cells showed little change in active sodium transport but, again, were much more permeable than normal.

DEXTROSE CONSUMPTION

Fig. 6 shows the results of estimates of dextrose concentration after various periods of storage at different temperatures. The rates of disappearance of dextrose in this experiment, expressed as mg. per g. of hæmoglobin a day, were calculated to be as follows:

At $+4^{\circ}\text{C}$ 0.62; at -10°C 0.084; at -20°C 0.008; at -79°C probably nil.

In a second experiment (not shown in fig. 6) the figures were as follows:

At -10°C 0.067; at -20°C 0.006; at -79°C probably nil.

Since it is of considerable interest to know whether dextrose concentration does diminish in red cells stored at -20°C the correlation coefficient for the observations shown in fig. 6 was calculated: -0.784 , S.E. 0.378; hence $0.02 < P < 0.05$.

In a further experiment the rate of dextrose consumption in mixtures containing respectively 25% and 50% glycerol (final concentrations) was compared. During storage at -20°C the mixtures containing 25% glycerol were solid, and those containing 50% glycerol were liquid. During a period of four months the consumption of dextrose did not differ significantly in the two mixtures.

PRESERVATION OF RED-CELL ANTIGENS

Tests were made to detect the following red-cell antigens in blood stored for a year at -20°C : A, B, M, N, S, D, C, c, E, P, Lu, Le^a, Le^b, K, and Fy^a. In all cases these antigens were still detectable, although the reactions were weaker than those given by fresh cells. There was considerable variation between blood samples: for instance, in some a particular antigen seemed to have deteriorated after three months' storage, whereas in others this antigen seemed almost unimpaired after a year's storage. It seems likely that the A antigen and the antigens of the Rh system deteriorate less rapidly than antigens of the other blood-group systems.

Discussion

The present results show that in an appropriate medium—e.g., solutions III and IV—red cells stored at -20°C not only undergo very little hæmolysis during

three months but retain, almost unimpaired, the ability to survive after transfusion. With longer periods of storage post-transfusion survival diminishes progressively. In other media—e.g., solutions I and II—red cells stored at -20°C show a progressive diminution in post-transfusion survival from the very beginning of the storage period. This pattern of survival of red cells stored in different solutions at -20°C strongly recalls the pattern observed in different solutions at $+4^{\circ}\text{C}$; this is illustrated by comparing figs. 4 and 5 with fig. 7.

Note that in A.C.D. solution at $+4^{\circ}\text{C}$ and in solutions III and IV at -20°C there is only a slight loss of viability for an initial period (fourteen days at $+4^{\circ}\text{C}$, and fourteen weeks at -20°C). Thereafter viability diminishes at an increased rate. By contrast, in trisodium-citrate solution at $+4^{\circ}\text{C}$ and in solution I at -20°C viability is lost rapidly from the beginning of the storage period. It does not seem likely that this big difference in behaviour in the different solutions can be explained by a slowing of chemical processes in the "favourable" solutions. It seems more probable that the rapid loss of viability in trisodium-citrate solution, both at $+4^{\circ}\text{C}$ and at -20°C , is due to physical damage. Lovelock (1954) estimated the lipid content of red cells stored for fourteen weeks in solutions I and IV and found that in solution IV there was no loss of cell lipids, whereas in solution I about 30% of the cell lipids was lost.

It seems likely that the damage observed in red cells stored in solutions I and II is due to the alkalinity of these mixtures. In the two solutions (III and IV) in which viability is well maintained at -20°C buffer systems are present: potassium dihydrogen phosphate and dipotassium hydrogen phosphate in solution III, and trisodium citrate and disodium hydrogen citrate together with a relatively large volume of plasma in solution IV.

Possibly further improvement in the maintenance of viability at -20°C could be obtained by modifying one of the solutions described here—e.g., the optimal pH may be different from that of the present mixtures. However, the fact that chemical change takes place at -20°C , shown by the consumption of dextrose, suggests that preservation for an indefinite period cannot be expected at this temperature.

In this connection some results published previously by Ross et al. (1947) are of the greatest interest. The survivals in vivo of red cells stored in Alesver's solution at 25°C and at 4°C were compared. The period of storage after which post-transfusion survival decreased to 50% was just under three days at 25°C and about seventeen days at $+4^{\circ}\text{C}$ —i.e., a fall in temperature of 21°C was associated with about a sixfold lengthening of the period during which the red cells maintained 50% viability. If the process responsible for the loss of viability were chemical, it would be expected that storage at -20°C —i.e., 24°C lower than $+4^{\circ}\text{C}$ —would lengthen the storage period rather more than sixfold. Fig. 5 shows that the viability of red cells stored in solution Iva at -20°C decreases to 50% after about thirty weeks. The viability of red cells stored at $+4^{\circ}\text{C}$ in A.C.D. solution decreases to 50% after about thirty-five days (fig. 7). Thus it seems that viability is maintained about six times as long at -20°C as at $+4^{\circ}\text{C}$. This is shown in another way by figs. 5 and 7, from which it will be seen that the loss of viability is very slow for fourteen days in A.C.D. at $+4^{\circ}\text{C}$, and for about fourteen weeks in solution IV at -20°C ; thereafter in both solutions the rate of loss of viability rises.

The results of only 4 transfusions of red cells stored at -20°C have previously been reported. Mollison et al. (1952) transfused red cells stored for twenty-nine, seventy-seven, and eighty-four days; in addition to the period of storage at -20°C the red cells had been kept ten days at $+4^{\circ}\text{C}$. Survival at twenty-four hours was 75-95% (average 82%), and the remaining cells dis-

appeared at about 1% a day. These red cells were stored in a mixture of their own plasma containing a proportion of A.C.D. solution and glycerol-saline solution. Although viability was well maintained in this solution, relatively rapid hæmolysis took place during storage, and it was for this reason that citrate was substituted for saline solution in the present solutions. Brown and Hardin (1953), who gave a transfusion of red cells stored fifty days in glycerol-lactate at -15°C , found a post-transfusion survival of about 50% and thought that the post-transfusion loss of red cells was due to failure to remove all the glycerol from the cells. However, the present results make it seem more likely that the loss was due to physical damage to the red cells during storage.

The results in table II show that red cells stored in sodium citrate (solutions I and IV) contain more sodium than potassium, whereas those stored in potassium citrate contain more potassium than sodium. It appears that the ratio of sodium to potassium does not affect survival in vivo, although there appears to be an association between total base content and viability. A reduction in cell volume, a loss of base, and a decrease in osmotic fragility appear to be associated with one another.

Cell shrinkage and loss of base do not seem to be due solely to the concentration of citrate in the medium. For example, cells stored for fourteen weeks in solution IVb, which has almost the same citrate content as solution I, show less shrinkage and a smaller loss of base than do cells stored in solution I. This difference may be due to the fact that cells stored in solution I suffer more physical damage than do cells stored in solution IV, or to the fact that solution IV contains some penetrating anions (Cl^{-}).

As mentioned above, there is some evidence that red cells stored in solution I become abnormally permeable to cations. Experiments have not yet been made to determine whether this permeability is reduced in solutions III and IV. Meanwhile it seems likely that the increased permeability is further evidence of physical damage occurring in solution I.

Although it may not be possible to maintain the viability of red cells for more than a few months at -20°C , even in buffered glycerol mixtures, it is of practical importance to know that the red-cell antigens are still detectable after at least a year's storage at this temperature. Grove-Rasmussen et al. (1953) have reported that red cells stored for twenty weeks in trisodium citrate at -20°C react as well as fresh cells. Our results suggest that there is considerable variation and that some antigens (such as P) undoubtedly deteriorate during this period and may not be detectable with weak antisera. However, many of the antigens are relatively well preserved and, in a laboratory where potent sera are used for genotyping, it has been found very convenient to keep a panel of cells of known groups readily available in a -20°C refrigerator.

In the present work on storing red cells for blood-grouping tests, only trisodium citrate/glycerol solution (solution I) was used. It is likely that better results would be obtained by using a solution—such as one with buffered phosphate (solution III)—in which red-cell viability is better maintained.

Summary

Red cells stored at -20°C in a solution of trisodium citrate (3%) and glycerol (30%) undergo only slow hæmolysis, but they rapidly lose their ability to survive after transfusion.

In modified citrate-glycerol solutions, the essential feature of which is probably the presence of buffers, survival is maintained, almost unimpaired, for about three months. Thereafter viability diminishes with time;

after thirty weeks' storage only about 50% of the red cells survive after transfusion. This slow loss of viability may be due to the fact that chemical change is not arrested at -20°C , and it is demonstrated that dextrose is in fact slowly utilised under these conditions.

Red cells stored for a year at -20°C in unbuffered citrate-glycerol mixtures react specifically with blood-grouping sera, although their reactions may be weaker than those of fresh cells.

We wish to thank Dr. J. D. James, Dr. P. D. Booth, and Dr. G. Plaut, of the North London Blood Transfusion Centre, for making blood available. Lederle Laboratories, New York, supplied the anti-M serum.

ORAL PENICILLIN

R. W. FAIRBROTHER

DEPARTMENT OF CLINICAL PATHOLOGY, UNITED MANCHESTER HOSPITALS

THE necessity for parenteral injection has been one of the major disadvantages of penicillin, and repeated attempts have been made to devise effective oral preparations. Trials with earlier products proved unsatisfactory because of poor and irregular absorption in spite of large dosage; so, supplies of penicillin being strictly limited, the oral route was not considered a practical proposition. Since then there has been a tremendous increase in the production of penicillin, with a great reduction in cost, and oral administration has been subjected to frequent investigation.

Benzathine penicillin, a new insoluble compound (N : N'-dibenzylethylenediamine dipenicillin G, known also as D.B.E.D. penicillin and benzethacil) has recently been produced, and preliminary tests by the oral route suggest that it gives reliable, effective, and prolonged blood-penicillin levels, particularly in children. As a result of these claims considerable interest has again been aroused in oral penicillin, and many different preparations are now available.

Controlled trials have so far been limited, but nevertheless the results have tended to be inconsistent:

Finberg et al. (1953) obtained excellent clinical results by treating pneumococcal and hæmolytic streptococcal infections in children with benzathine penicillin.

Coriell et al. (1953) reported good results, as well as satisfactory blood-penicillin levels, in the treatment of scarlet fever in children with the same compound.

Cathie and MacFarlane (1953) found some absorption of penicillin after a single dose of 300,000 units of benzathine penicillin in all of 118 people, of whom 101 were children.

Bayne et al. (1953) gave a single dose of 300,000 units of benzathine penicillin to 6 adults and found detectable blood-penicillin levels for four hours but not after six hours; and after a dose of 600,000 units, only 1 of 6 adults lacked a blood-penicillin level of 0.03 unit per ml.

Foltz and Schimmel (1953) showed that, after the administration of single doses of 300,000 units to the same 12 adults, higher blood-penicillin levels were obtained with potassium penicillin G and procaine penicillin than with benzathine penicillin, and that, with each preparation, penicillin was absent from some serum samples at the end of six hours.

Wright et al. (1953) gave tablets of different oral preparations to the same 12 persons in a dosage of 200,000 units and found that absorption was more consistent with buffered potassium penicillin G than with benzathine penicillin.

Welch et al. (1953) estimated the blood-penicillin levels of ambulant adults at intervals after oral administration of benzathine penicillin in tablet form. Penicillin was usually detected for two or three hours after a dose of 200,000 units; with larger doses, up to 750,000 units, absorption was more consistent, and the blood-penicillin levels tended to be higher and more prolonged; there was, however, considerable individual variation in the amount of absorption, levels of only 0.012 unit per ml. being recorded in some cases.

In view of these irregular results it seems important that further information should be obtained about oral penicillin, so that its scope and limitations can be more clearly defined. Consequently we made tests, mainly in adults, to determine particularly the degree of absorption after a single dose of various oral preparations; at the same time we undertook a few clinical trials.

Methods

The various preparations were usually given before breakfast, and in many instances the dose was accurately measured. At times teaspoons were used, but these vary considerably in capacity, moderate to large types usually holding 3-5 ml., and accurate dosage is impossible; but in this trial there was usually a close approximation to the desired amount.

Samples of blood were collected at definite intervals, and the blood-penicillin levels were estimated by a standard serial-dilution technique using *Staphylococcus aureus* (Oxford) as the test organism. When any delay in making the tests was likely, the serum was kept in the refrigerator until required.

Results

Previous findings indicate that there is considerable individual variation in the amount of absorption after the oral administration of penicillin. It was consequently considered that more valuable information would be obtained by making single estimations in a large number of people rather than by making many estimations in a few. This was the main object of the investigation, and 330 tests have been made on patients and volunteers.

TABLE I—BLOOD-PENICILLIN LEVELS AFTER A SINGLE DOSE OF BENZATHINE PENICILLIN

Group	Dosage (units)	Time after dose (hr.)	Blood-penicillin (unit per ml.)						No. of persons	
			None detected	0.03	0.06	0.125	0.25	0.5		1 or more
Adults	300,000	2-3 5	4 3	5 3	2 1	8 3	1 0	0 0	20 10	
	600,000	1-3 5-6	1 11	10 11	14 23	18 13	19 1	5 0	1 0	68 59
Children	300,000	2-3 4-6	0 0	0 2	3 3	1 1	8 1	2 1	0 2	10 10
	600,000	3	0	2	5	2	2	0	0	11
								Total	188	

TABLE II—BLOOD-PENICILLIN LEVELS IN ADULTS AFTER A SINGLE DOSE OF SOLUBLE PENICILLIN G

Dosage (units)	Preparation	Time after dose (hr.)	Blood-penicillin (unit per ml.)						No. of persons	
			None detected	0.03	0.06	0.125	0.25	0.5		1 or more
300,000	Eskacillin	1-3 4-6	1 2	3 3	5 2	6 3	5 0	2 2	5 0	27 12
		Pradupen	1-3 4-6	0 0	0 1	0 3	0 3	0 2	1 0	0 0
600,000	Eskacillin		1-3 4-6	0 0	1 5	5 8	4 10	17 4	11 1	8 2
		Pradupen	1-3 4-6	0 1	0 3	0 1	0 0	2 0	5 0	5 0
								Total	142	

Two distinct types of oral penicillin have been used: (1) the insoluble benzathine penicillin ('Penidural,' Wyeth); and (2) soluble compounds: (a) potassium penicillin G ('Eskacillin,' Menley & James), and (b) potassium salt of benzylpenicillin B.P. ('Pradupen,' Evans Medical Supplies).

BENZATHINE PENICILLIN

Penidural is a stable and palatable suspension, which is well tolerated. A single dose of 300,000 or 600,000 units was given to 181 people (150 adults and 31 children). Usually, only one sample of blood was taken from each person; it was collected either two or three hours after oral administration which is considered to be the peak period of absorption, or after five or six hours (table I).

There was no uniform pattern of absorption, and the blood-penicillin levels showed considerable individual variation irrespective of the dosage.

In adults a dose of 300,000 units gave disappointing results and was discontinued because occasionally there appeared to be little or no absorption. Better results were obtained with a dosage of 600,000 units. A detectable blood-penicillin level was found within three hours of administration in 67 of 68 assays, and in 6 instances a level of 0.5 unit per ml. or more was obtained. After five or six hours 37 of 59 persons still had levels of 0.06 unit per ml. or more.

Only a limited investigation was made in children, but the results were more striking: evidence of absorption was found in all the cases, and 2 young infants had 1 or 2 units per ml. from four to six hours after a dose of 300,000 units. A dose of 600,000 units did not produce any increase in the blood-penicillin levels.

These irregular results are not surprising, because penidural is an insoluble compound and probably has to be broken down in the alimentary tract to liberate a soluble form of penicillin G. The precise mechanism of the reaction has not been determined, but Lozinski and Gleason (1953) consider that the complex penicillin compound undergoes rapid hydrolysis in normal gastric juice and some hydrolysis in an alkaline medium. Considerable individual variation might therefore be found in not only the release of soluble penicillin from the compound but also its subsequent absorption.

In some cases blood-penicillin levels were estimated five or six hours after a second or third dose of 600,000 units, and evidence of a cumulative response was usually, but not invariably, found.

11 men with acute gonorrhoea were treated with penidural. 2 of them each received one dose of 600,000 units; there was an immediate improvement, but both cases relapsed. 9 of them were given a second dose of

600,000 units after an interval of six hours; 7 of these were cured, and 2 relapsed.

SOLUBLE COMPOUNDS

The two compounds eskacillin and pradupen are similar preparations which vary slightly in composition and method of preparation. Eskacillin is crystalline potassium penicillin G which, when required for use, is dissolved in a special flavoured and buffered solution. It is palatable and, at room-temperature, retains its potency for at least seven days. Pradupen is a powder containing potassium benzylpenicillin as well as buffering and flavouring agents; solution is effected by the addition of tap-water.

These preparations were given to 142 adults, and the resulting blood-penicillin levels are given in table II.

Irregular readings were again obtained in a similar group of adults; but usually absorption was quicker and blood-penicillin levels tended to be higher than with penidural.

With a dose of 300,000 units high blood-penicillin levels (1 unit per ml. or more) were obtained at the peak period in a few cases, but in 1 instance absorption was not detected, and on several occasions levels of 0.03 unit per ml. were found. Better results were produced by increasing the dose to 600,000 units, when all the 58 persons gave evidence of absorption at the peak period, the range varying from 0.03 to 1 unit per ml. With eskacillin some penicillin was still present in all of 30 cases at the end of from four to six hours.

15 male cases of acute gonorrhoea were each treated with two doses of 600,000 units, the second dose being given after an interval of six hours; all showed rapid improvement, but with eskacillin 2 of 7 cases relapsed. Another case was treated with pradupen in two doses of 400,000 units, with an interval of six hours, but relapsed after an initial improvement.

Discussion

It is generally accepted that a variable, and sometimes small, proportion of penicillin is absorbed after oral administration, and consequently this route is not recommended in the initial stages of acute severe infections. These views are supported by the results of the present investigation. Absorption after oral dosage was irregular, irrespective of the nature of the penicillin compound or the age of the recipient.

The present work was mainly concerned with adults, in whom a dose of 300,000 units gave disappointing results. In a few instances there was no evidence of absorption, and in some cases the absorbed penicillin was eliminated within six hours. Better results were given with a dose of 600,000 units, but there was again found considerable inconsistency not only in the peak blood-penicillin levels but also in the persistence of penicillin in the blood. In the great majority of tests made up to three hours after administration—i.e., the peak period—blood-penicillin levels of at least 0.03 unit per ml. were obtained, and in many of them considerably higher levels were found.

It is often stated that 0.03 unit per ml. represents the minimal effective level of penicillin, but this figure has little, if any, therapeutic significance. It can be readily demonstrated by in-vitro tests that, with moderate numbers—e.g., 2,000,000 per ml.—of a sensitive strain of *Staph. aureus*, a level of 0.03 unit per ml. of penicillin has merely a transient bacteriostatic effect, whereas a level of 0.3 unit per ml. has considerable bactericidal activity. With a pneumococcus, which is a highly sensitive organism, a level of 0.03 unit per ml. may, however, have some bactericidal effect.

The blood-penicillin level is not a direct index of therapeutic activity, because many other factors, including the sensitivity and accessibility of the infecting organisms,

must also be considered. There is, however, little doubt that, in most acute infections, levels of 0.03 unit per ml. are likely to have limited therapeutic activity.

In the present investigation blood-penicillin levels of 0.03 unit per ml. or less have been obtained in each group of subjects with all the preparations used; moreover it is impossible to predict when absorption is likely to be so small. It must therefore be emphasised that in the treatment of acute infections, even with sensitive organisms, the initial doses of penicillin should be given parenterally to ensure rapid bactericidal activity. When the clinical response to parenteral penicillin is satisfactory, continuation treatment with oral preparations should prove adequate in most cases; this form of therapy should be particularly advantageous in children, in whom parenteral injection may be a very disturbing experience. Oral administration may also prove useful when the prophylactic use of penicillin is considered advisable.

It has been shown that, by combination with probenecid, which delays the renal excretion of penicillin, oral products give consistently higher and more prolonged levels. Severe reactions to penicillin are becoming a serious problem; and, though oral administration reduces, but does not eliminate, this risk, the combination of penicillin with another potential sensitising agent may not be entirely beneficial.

The main advantage of oral penicillin is convenience of administration; but, even with the new products, there still remains the serious objection of irregular, and sometimes poor, absorption, particularly in adults. It must also be realised that oral administration constitutes a relatively expensive form of penicillin therapy. A dosage of 300,000 or 600,000 units six-hourly costs considerably more than a daily injection of 400,000 units of procaine penicillin, which gives similar, but more uniform, blood-penicillin levels (Fairbrother and Daber 1950).

The increasing number of potent antibiotics, the great variety of proprietary preparations, and the potential dangers of these agents necessitate a careful assessment of each case before advising any form of antibiotic therapy. It is therefore important that convenience of administration should not lead to widespread and indiscriminate use of oral penicillin, especially in the treatment of minor infections.

Summary

Blood-penicillin levels have been estimated on 330 occasions after the oral administration of various preparations of penicillin.

A single dose of 300,000 units gave disappointing results in adults.

Absorption was more consistent after a dosage of 600,000 units, but considerable variation was found in the amount absorbed by different people.

It is a pleasure to thank our medical colleagues and the nurses for their ready co-operation throughout this investigation. Messrs. J. Wyeth & Brother Ltd., Menley & James Ltd., and Evans Medical Supplies Ltd. supplied the oral preparations of penicillin.

**BENZATHINE PENICILLIN
BY MOUTH IN CHILDREN**

D. M. G. BEASLEY

M.B. N.Z., M.R.A.C.P., D.C.H.

LECTURER, DEPARTMENT OF CHILD HEALTH,
UNIVERSITY OF SHEFFIELD

M. J. MACPHERSON

B.Sc., Ph.D. Edin.

BACTERIOLOGIST, PATHOLOGY DEPARTMENT,
CHILDREN'S HOSPITAL, SHEFFIELD

AN effective, reliable, and inexpensive oral penicillin preparation is much to be desired. N,N'dibenzylethyl-enediamine penicillin (benzathine penicillin or 'Penidural'), which has been suggested as such a preparation, is a sparingly soluble compound of penicillin first described by Szabo et al. (1951) and Seifter et al. (1951). Lepper et al. (1952) estimated the blood-penicillin levels obtained after the oral administration of benzathine penicillin to children aged less than 5 years and found blood-penicillin levels of not less than 0.03 unit per ml. of serum in five of seven children six hours after the administration of 250,000 units. Coriell et al. (1953), who administered benzathine penicillin to nine children aged 4-11 years in a dosage of 7000 units per kg. body-weight, reported that none of them had a serum-penicillin level as high as 0.03 unit per ml. at six hours. Cathie and MacFarlane (1953) showed that benzathine penicillin 300,000 units, given orally to 95 children weighing 10-70 lb., produced a serum-penicillin level of not less than 0.03 unit per ml. three hours after administration. The serum-penicillin levels at four and six hours after administration were not recorded.

The trial of benzathine penicillin reported here was planned to establish for children a scheme of dosage,

Serum-penicillin levels with repeated doses of benzathine penicillin 600,000 units four-hourly in a child weighing 40 lb.

based on body-weight, which would maintain a constant serum-penicillin level of at least 0.03 unit per ml.

Materials and Method

Penicillin-serum levels were estimated by a capillary technique using a strain of *Streptococcus pyogenes* as the assay organism.

Assays were made in each child before the start of treatment to ensure that there was no penicillin present in the serum.

Benzathine penicillin was given, irrespective of meal-times, in single doses of 5, 10, 15, and 20 ml. (5 ml. = 300,000 units of penicillin) to children in different weight-groups, and serum-penicillin levels were estimated at regular intervals up to six, eight, or twelve hours after its administration. The possible cumulative effect of repeated six-hourly doses on the serum-penicillin level was also studied.

Results

The minimal satisfactory serum-penicillin level was taken as 0.03 unit per ml.

Benzathine penicillin was rapidly absorbed, and satisfactory serum-penicillin levels were found an hour after administration. Thus the dose which at six hours produced satisfactory serum-penicillin levels produced at an hour in 28 of the 30 patients serum-penicillin levels of 0.125-1.000 units per ml. From three to six hours the serum-penicillin levels fell steadily.

The results summarised in table I show that 300,000 units of benzathine penicillin maintained a satisfactory serum-penicillin level for four hours in children weighing up to 40 lb., and for six hours in children weighing up to 25 lb.; and 600,000 units of benzathine penicillin was needed to maintain a satisfactory serum-penicillin level

TABLE I—PENICILLIN-SERUM LEVELS AFTER ADMINISTRATION OF ORAL BENZATHINE PENICILLIN

Dose (units)	Interval after administration (hr.)	Weight range (lb.)	Patients showing satisfactory serum-penicillin levels
300,000	4	0-40	19 of 19 (100%)
		<40	0 of 7 (0%)
		0-25	8 of 8 (100%)
600,000	6	25-40	0 of 13 (0%)
		40-70	16 of 17 (94%)
		<70	6 of 16 (37%)
900,000	6	25-40	7 of 9 (78%)
		40-70	6 of 29 (24%)
		<40	8 of 9 (89%)
1,200,000	8	40-70	5 of 9 (55%)
		<70	2 of 8 (25%)
		<70	11 of 11 (100%)
8	8	<70	8 of 11 (82%)
		<70	4 of 6 (67%)
		<70	

for four hours in children weighing 40-70 lb., and for six hours in children weighing 25-40 lb. In heavier children even higher doses were needed to maintain satisfactory serum-penicillin levels throughout the six hours between doses. Serum-penicillin levels estimated in 6 patients during a course of treatment were not significantly higher than those obtained after a single dose of benzathine penicillin. A typical example is shown in the accompanying figure.

From the results in table I a scheme of dosage is suggested (table II). Six-hourly doses of benzathine penicillin should be about 12,000 units per lb. body-weight, and four-hourly doses about 8000 units per lb. body-weight.

With a few exceptions children liked the flavour of benzathine penicillin. It was not, however, free from side-effects. There were no rashes, but of 131 children treated with benzathine penicillin 26 had loose stools and 3 had some nausea and vomiting. In no case, however, were these symptoms really troublesome.

Summary

Benzathine penicillin was given by mouth to children of different ages, and serum-penicillin levels were estimated.

Benzathine penicillin 300,000 units ('Penidural' 5 ml.) maintained satisfactory serum-penicillin levels for four hours in children weighing up to 40 lb. and for six hours in children weighing up to 25 lb., and 600,000 units for four hours in children weighing 40-70 lb. and for six

TABLE II—SCHEME OF DOSAGE BASED ON BODY-WEIGHT FOR BENZATHINE PENICILLIN

Weight (lb.)	Interval between doses (hr.)	Units of benzathine penicillin (300,000 units = 5 ml.)
0-25	6	300,000
25-40	4	300,000
		600,000
40-70	6	900,000-1,200,000
>70	6-8	1,200,000

hours in children weighing 25-40 lb. Heavier children required correspondingly higher doses.

A scheme of dosage based on body-weight is suggested for children.

It is a pleasure to acknowledge the help and encouragement given to us by Prof. R. S. Illingworth and Dr. J. L. Emery. Messrs. John Wyeth Ltd. supplied the penidural.

TREATMENT OF MOLLUSCUM SEBACEUM

R. FINNEY

M.B. Lond., F.R.C.S.E., D.M.R.T.

ASSISTANT RADIOTHERAPIST, ST. THOMAS'S HOSPITAL, LONDON

THE condition known alternatively as molluscum sebaceum, kerato-acanthoma, or molluscum pseudo-carcinomatousum is now an established entity becoming increasingly well recognised (MacCormac and Scarff 1936, Musso and Gordon 1950, Rook and Whimster 1950, Beare 1953). The treatment of these cases is still, however, not generally agreed on (Beare 1954, Halnan 1953, 1954, Gold 1954). Indeed molluscum sebaceum is a self-limiting self-healing condition, and it might be argued that any treatment is therefore unnecessary. Against this its natural course may last up to six months, during which time the patient is left with an unsightly ulcerating tumour; hence treatment would appear to be justifiable to limit the life-cycle of the tumour and procure early healing.

Diagnosis

The danger of mistakenly diagnosing and treating a squamous epithelioma as molluscum sebaceum has been emphasised (Halnan 1953, 1954). Such difficulties may arise during the first two months of the tumour's life—i.e., before the formation of the central keratin plug. An adequate and representative biopsy specimen, however, examined by a pathologist familiar with the histological structure of molluscum sebaceum, taken in conjunction with the clinical history and findings, should make the diagnosis certain, in all cases. There is no doubt, however, that in the past many of these cases have been treated as squamous epitheliomata; hence statistics of treatment of epitheliomata should be reviewed in the light of recent knowledge. Once the keratin plug has been formed, the diagnosis is usually obvious clinically. If any doubt persists, the histological findings will once again be confirmatory. In short, the difficulties of diagnosis in these cases should be dealt with as for basal-cell carcinoma, squamous papillomata, or other conditions which may be confused with squamous epitheliomata—i.e., if in doubt biopsy and if necessary re-biopsy, rather than if in doubt treat all as epitheliomata.

Treatment

There appears to be two main methods of treating this condition: surgical removal, and radiotherapy.

SURGICAL REMOVAL

Surgical procedures have included diathermy or electrolysis, local excision and suture, and excision or curettage of the superficial parts of the tumour followed by cautery or application of caustics to the base.

MacCormac and Scarff (1936), describing their original 10 cases, recommended electrolysis followed by the application of carbon-dioxide snow. There were no recurrences among these cases.

Beare (1953) reports on treatment by combined curettage and diathermy in 76 cases with excellent cosmetic results. In 27 of these cases curettage was followed by a single exposure of superficial X rays in a dosage of 800-1200r. This post-operative irradiation has now been abandoned because "there is little if any advantage in giving X rays in addition to curettage." One case was noted in this series which had recurred after previous diathermy.

I. W. Whimster (personal communication) reports on 40 cases treated at St. Thomas's Hospital by surgical excision under local anaesthesia. Many of these lesions were unduly large, compared with the maximum of 1.0-1.5 cm. in diameter cited by Beare (1953).

RADIOTHERAPY

The treatment of molluscum sebaceum by radiotherapy has been likened to "using a sledgehammer to drive in a nail" (Beare 1954), and has been criticised on the grounds that large doses of either radium or X rays have to be used. The earliest cases of molluscum sebaceum were referred to the radiotherapy department at St. Thomas's Hospital in 1949, when the condition was not so well recognised and little was known about the preferential form of treatment. It was felt that treatment by radiotherapy alone could play a part in the treatment of the condition just as in other benign skin lesions—e.g., haemangiomata, keloid scars, and plantar warts—and without resorting to a "sledgehammer" dosage. It was therefore in an attempt to determine the optimum dosage to cause regression of the tumour that the following 25 cases were treated by radiotherapy alone.

Technique

Identical methods were used in treating all the cases. A Chaoul tube was used delivering X rays at a voltage of 60 kV, 4 mA, and a half-value layer of 3.3 mm. of aluminium. The volume of tissue irradiated was confined to an amount just wide of the lesion. The treatment was given as a single exposure but in varying dosage. After treatment the area treated was inspected weekly or fortnightly so that the degree of reaction and the rate of regression of the tumour could be assessed. In 6 of these cases treated by varying dosage a biopsy specimen

RESULTS OF RADIOTHERAPY

Case no.	Dose (r)	Degree of reaction †	Tumour-regression time (weeks)	Reaction-regression time (weeks)
<i>Group A:</i>				
1	2500	3	4	8
2	2500	3	3	8
3	2500	3	4	7
4	2250*	3	3	6
<i>Group B:</i>				
5	2000	3	4	7
6	2000	2	4	5
7	1800	2	4	5

23	1250*	1	8	3
24	1250	1	6	4
25	1200	1	6	4

Average tumour-regression time in groups B and C = 4 weeks.
 Average reaction-regression time in groups B and C = 4½ weeks.
 * Cases subjected to post-irradiation biopsy.
 † 1, erythema only.
 2, erythema + dry scaling.
 3, erythema + vesicle formation + ulceration.

was taken of a representative portion of the tumour a week after irradiation and submitted to histological examination.

Results

Of the 25 cases of molluscum sebaceum treated by radiotherapy alone 5 had been treated by other methods previously. 1 case had been treated on three separate occasions: twice by local excision, and once by application of carbon-dioxide snow. 2 other cases had recurred after local excision on one occasion each, and of 2 other recurrences 1 had followed local applications of caustics and the other removal by diathermy.

The accompanying table shows the dosage given, the degree of reaction, and the length of time taken until the tumour had regressed completely and the reaction healed. In all the cases the cosmetic result has been good, leaving a typical flat slightly depressed scar. No recurrence has yet been noted after radiotherapy alone. An attempt has been made to assess these results from two aspects: (1) the rate of tumour regression correlated with the quantity of irradiation and hence also with the reaction produced; and (2) in cases subjected to post-irradiation biopsy, the quantitative cytological changes resulting, correlated with the quantity of radiation given.

From the table it will be seen that there are four separate dosage levels:

Group A.—A dosage equivalent to that used in treating squamous epitheliomata—2250–2500r. In all the cases the reaction was severe, labelled as 3rd degree, and because of this the rate of regression of the tumour was difficult to assess accurately. The reaction subsided in 6–8 weeks and tumour regression was complete by 4 weeks.

Group B.—A "subradical" dose was given—1750–2000r. The resulting reaction was less, being 3rd degree in only 1 case, and 2nd degree in the remainder. Tumour regression was complete in 4 weeks, and reaction healing lasted correspondingly shorter than in group A and was complete in 4–6 weeks.

Group C.—The dosage given was 1500r. The reaction was 2nd degree only and had settled within 3–6 weeks. Tumour regression took place within 3–5 weeks.

Group D.—The dosage used was roughly half that given for the radical treatment of squamous carcinomata—1200–1250r. The reaction was 1st degree in all the cases, being healed in 3–4 weeks. The rate of tumour regression was, however, appreciably slower than in the preceding groups, taking 6–8 weeks to be completed.

The average tumour-regression time for all the groups was about $4\frac{1}{2}$ weeks, and for groups B and C about 4 weeks. The average reaction-regression time for all the groups was about 5 weeks, and for groups B and C about $4\frac{1}{2}$ weeks.

This analysis shows that at the extremes of dosage levels the resultant tumour regression/reaction ratio is disproportionate. In group A the reaction produced was excessive, the dose level being too high. In group D the tumour-regression rate was appreciably slower, suggesting that the dosage was too low. The optimal range of dosage producing a satisfactory tumour-regression rate without an excessive degree of reaction therefore seems to be that used in groups B and C—i.e., 1500–1750r. The 1500r dose produced slightly less reaction than the higher dosages, and this therefore seems to be a satisfactory dosage. In bulkier lesions probably the larger dose of 1750r should be used.

Attempts to correlate cytological response with dosage have been more difficult because of the small numbers dealt with. In 6 cases biopsy specimens taken after irradiation at different dosage levels were submitted to histological examination, which showed that cytological changes due to irradiation were present in all specimens studied, but quantitatively there appeared to be little difference in the number of cells damaged irrespective of the dosage at 1250 or 2250r. It must, however, be emphasised that the numbers dealt with were small, and a

larger series would have to be studied before a definite conclusion could be drawn.

Conclusions

Molluscum sebaceum may be effectively treated by radiotherapy. Histological examination after irradiation of these tumours suggests that there is little quantitative difference in cytological damage over a wide range of dosage. A satisfactory tumour-regression rate follows a dosage level of 1500–1750r. A dosage above this produces an unnecessarily more severe and prolonged reaction.

Summary

The diagnosis and results of various surgical treatments of molluscum sebaceum are reviewed.

The treatment of 25 cases by radiotherapy alone is reported, and the results are analysed.

Four groups of dosage levels were used and correlated with reaction and tumour-regression rate.

Correlation with cytological response in 6 cases showed little quantitative difference at various dosage levels.

I wish to thank Dr. J. A. C. Fleming, director of the department of radiotherapy, St. Thomas's Hospital, for his help and encouragement in publication, and Dr. I. W. Whimster for the histological reports on the biopsy specimens, and for permission to review his cases which were treated surgically.

SPONTANEOUS RUPTURE OF THE BLADDER

J. M. TAINSH

M.B. Lond., F.R.C.S., M.R.C.P.

GENERAL PRACTITIONER, CHAPLEAU, ONTARIO

THIS case is recorded because of the rarity of spontaneous rupture of the bladder. The events took place in private practice in a small isolated community, with no ready source of reference, so I shall refrain from comment, other than to reiterate the admonitions of one of my late chiefs, "Watch the bladder," and to point out the relative harmlessness of non-infected urine spilt intraperitoneally, so long as it is removed at once.

A man, aged 65, slipped in the snow on Jan. 1, 1952, and injured his left hip. He crawled some distance to a road, where he was picked up by a passing lorry and brought into town.

Examination.—showed a fractured left femoral neck; this was confirmed by radiography on admission to hospital. He was put to bed, and traction was applied to the leg with adhesive plaster. During the period of delay before open reduction could be carried out (occasioned by seasonal lack of staff) the patient complained of difficulty in micturition, on one occasion only. On the afternoon of Jan. 2 he could not urinate; so the orderly was instructed to catheterise him, which he did with ease.

Operation.—On the morning of Jan. 6 open reduction of the fracture was done under spinal anaesthesia, and a Smith-Petersen nail was inserted in the usual manner.

Progress.—Next day exercises of the hip were started. Each day the patient appeared rather depressed and irritable, being worried about his heart, having been told on some previous occasion that it was weak. He had some difficulty in urinating and frequently asked for the bottle; but although he passed adequate quantities of urine, he must have had some retention. On the morning of Jan. 10 he developed severe epigastric pain after using the bedpan. When I saw him he was

shocked and in great discomfort. His abdomen was very tender and as hard as a board. Perforated peptic ulcer was diagnosed, and a long history of indigestion elicited to suit the diagnosis!

Laparotomy was done two hours later through an upper right paramedian incision. Much clear fluid was found, but no perforation, after diligent exploration of the stomach, although a sessile papilloma was found high up on the anterior surface. The possibility that the fluid might be urine was confirmed by feeling a small contracted bladder with a hole at its apex exactly like an old-fashioned ink-well. Through a lower midline incision a perforation was found on the posterior surface of the bladder about midway between its base and its apex. The bladder was opened through the retropubic space. The prostate was not enlarged, and the internal meatus appeared normal. The rent was sutured intravesically with interrupted catgut and reinforced intraperitoneally. The bladder was closed about a large rubber tube, a drain inserted to the retropubic space, and the incision closed in the usual manner. The gastric papilloma (which proved to be a leiomyoma) was excised with an inch margin of healthy stomach wall and the deficiency closed with two layers of continuous catgut.

Postoperatively I discovered that in 1944 the patient had undergone a transurethral resection for impaction

of a stone in his urethra. Since then he had had no urinary symptoms. He was now treated by continuous gastric suction, intravenous fluid containing oxytetracycline, and 'flocillin D.S.' (a repository penicillin-streptomycin mixture). On Jan. 14 the gastric suction and the intravenous fluid were discontinued, and the patient began to take fluids by mouth. The flocillin was continued prophylactically until Jan. 20 in view of the assortment of surgical wounds. The suprapubic drain was removed on Jan. 18 and a self-retaining catheter inserted after sounding the urethra. On Feb. 2 the suprapubic wound appeared dry and the catheter was removed. The patient, however, had some difficulty in micturition, and urine soon began to leak suprapubically. The catheter was reinserted, and drainage was continued until Feb. 14, when the catheter was removed and the patient could urinate freely. On this date he was transferred to a urologist in Sudbury, Dr. M. L. Mader, who reported scarring at the vesical neck and did a transurethral resection.

Follow-up.—The patient made an uneventful recovery and is now in excellent health and able to walk ten miles daily without difficulty.

I wish to thank my partner, Dr. K. C. Soper, whose skill in anaesthesia made possible the successful outcome.

Reviews of Books

The Health of the Community

C. FRASER BROCKINGTON, M.A., M.D. Camb., D.P.H., barrister-at-law, professor of social and preventive medicine, University of Manchester. London: J. & A. Churchill. 1954. Pp. 400. 32s.

THE factual content of this book is not so very different from that of other books of like title and subject, yet it is bright with new approach. The pieces of paper one puts into a kaleidoscope are only pieces of paper, but they become changed to patterns. Professor Brockington composes his pattern finely and has the power of capturing in few words a meaning, a doubt, an explanation, or a reassurance. Admittedly there are a few slips here and there—one in the author's words on child minding, and another in the section dealing with housing and standards of overcrowding. But this is not a work of reference, nor another primer of public health. Read as a whole or in part, it provides plenty of material for serious discussion and readers will argue, for example, over Professor Brockington's forthright claim that the future medical officer of health should coördinate all community health and welfare services. (Some of them may also argue over his horrifying statement that "Mary, Queen of Scots, does not seem very beautiful now by her pictures; she may have been thought a beauty . . . because of the fact that she had never been disfigured by smallpox.") The book is comprehensive, dealing historically and critically with the functions of the medical officer of health and nearly every aspect of his work.

Synopsis of Children's Diseases

JOHN RENDLE-SHORT, M.A., M.B. Camb., M.R.C.P., D.C.H., senior registrar, department of child health, Welsh National School of Medicine. Bristol: John Wright. 1954. Pp. 620. 32s. 6d.

THE "Synopsis" series have a reputation for authority combined with brevity. This youngest member of the series, appropriately enough, deals with children's diseases, and it lives up to the standard of its predecessors. The staccato style, reminiscent of Mr. Jingle, does not make for easy reading; but then the book is not intended to be read in the normal manner but to be used for rapid revision and easy reference. As nothing of importance has been omitted, it will be helpful to undergraduates to have most of the diseases described as common, rare, or very rare. (Two major triumphs of preventive medicine are well demonstrated by the classification of rickets and diphtheria as very uncommon diseases.) The text is much more up to date than are most textbooks by the time that they reach publication. Such comparative newcomers as idiopathic pulmonary

hæmosiderosis, hyaline membrane disease, and idiopathic hypercalcaemia are given brief but suitable descriptions.

The first section, dealing with normal growth and development and with infant feeding, lays particular stress on breast-feeding, and there is an excellent section on the newborn infant, with a sensible note on the psychological aspects of prematurity (which may affect the relation between the mother and child). Each main section has an introductory note on normal variations of infancy and childhood, and on special methods of investigation and examination. The tables of differential diagnosis of such symptoms and signs as jaundice, muscle wasting, stridor, and hæmatemesis are useful, and the section on the treatment of dehydration is particularly good. At the end of the book there is a list of the dosage of some common drugs for various age-periods from the newborn infant up to the age of 9 years. A surprising omission is the absence of any reference to the use of isoniazid in the treatment of tuberculosis—no doubt an oversight.

This is a work that should be deservedly popular, not only with examination candidates but also with doctors in practice.

Handatlas der Cystoskopie und Urethrocytoskopie (3rd ed. Leipzig: Thieme, 1953. Pp. 110. DM. 50).—This book consists mainly of paintings; and the late Prof. O. Kneise and Dr. M. Stolze, the authors, both experienced urologists, were themselves the artists. The first edition was published as long ago as 1907. There are 124 paintings, all in colour, arranged in seven sections depicting various types of bladder lesion, each section preceded by a brief discussion of the disease to be illustrated and the part played by cystoscopy in its diagnosis and treatment. There are some rather more general articles on the cystoscope and its use at the beginning of the book. The quality of the pictures is on the whole very good, though it does vary: thus the only nine pictures of urethrocytoscopic findings are poor. A still picture in one plane of one cystoscopic field is necessarily a fragmentary and artificial representation of the living bladder disorder, no matter how excellent the painting. This atlas cannot escape this limitation, but it provides interest, pleasure, and some instruction.

The Silent Shore (London: Hodder & Stoughton, 1954. Pp. 384. 12s. 6d.).—In this book by Mr. Denis B. Wylie, a strong-minded woman doctor, having delivered a school-friend of twins, a boy and a girl, takes an interest in the future history of the babies and the rest of the family, and extracts from her diary fill in the gaps in the narrative. Mr. Wylie's ebullience leads him to offer his readers a plot with too many incidents, lively conversations with too many jokes, and discussions on too many social problems. But his humanity ensures that none of these are trivial, and his hero's interest in the problems of the aged is an important part of the book. The book is pleasant reading, though perhaps not for strong-minded women doctors.

HYDROCORTISONE

MADE IN ENGLAND

CORTISONE

HYDROCORTISONE ACETATE

Local injection, 25 mg. per cc. ; 5 cc. vials
 Skin ointment, 1% & 2.5% ; 5 G tubes
 Eye drops, 1% suspension ; 3 cc. dropper bottles

CORTISONE ACETATE

QUIET,
UNINTERRUPTED
SLEEP**

In the treatment of unproductive cough in children and adults the advantages of ETHNINE lie in its effectiveness with low toxicity, and its freedom from side-effects such as constipation and digestive upset.

For children, ETHNINE is indicated whenever a cough sedative is considered advisable particularly in the treatment of whooping cough, irritation of the upper respiratory tract, and the cough associated with enlarged tonsils and adenoids before surgical measures are taken.

The sedative action of ETHNINE is particularly useful when it is desired to ensure a restful night's sleep uninterrupted by paroxysms of coughing.

Pernicious Anæmia—a General Disease

PERNICIOUS anæmia is a misleading title. The disease is no longer "pernicious," since it can be successfully treated and controlled; and anæmia is only the most prominent of its manifestations. The curious megaloblastic change in the erythroblasts is not the only abnormality in the bone-marrow cells. The granulocytes also are affected; the leucopenia and the presence of multilobed polymorphs were known to the earliest investigators, and bone-marrow studies have shown significant gigantism among the metamyelocytes—the nucleus is unusually large and occupies more of the cell than normally. Another recognised complication of pernicious anæmia is a low platelet-count, sometimes with serious hæmorrhage. This again is now known to be paralleled by abnormalities in the platelet-producing cells of the bone-marrow—the megakaryocytes. EPSTEIN¹ has studied the megakaryocytes in bone-marrow biopsies of patients with pernicious anæmia in relapse, and in some found giant megakaryocytes with excessive nuclear segmentation. KISSMEYER-NIELSEN² thought that the megakaryocytes might not be producing platelets, and such platelets as could be found were large and coarse; but the number of megakaryocytes was normal. All these changes in the granulocytes and in the megakaryocytes are reversed when vitamin B₁₂, or any active treatment, is given.

The pathological changes in the nervous system that accompany pernicious anæmia have been known for over half a century. At one time it was suggested that these were due to a different deficiency from that responsible for the blood changes. Thus Sir ARTHUR HURST postulated the presence of a factor, "neuro-poietin" (to contrast with hæmopoietin, the gastric intrinsic factor), that was necessary for the proper nutrition of cells in the spinal cord: the clinical syndrome of subacute combined degeneration of the spinal-cord tracts was the clinical expression of deficiency of this factor—a deficiency that might develop independently of hæmopoietin deficiency, thus accounting for the non-anæmic cases of the syndrome. But today it is recognised that vitamin B₁₂, a single substance which effectively corrects the anæmia, will also bring about certain arrest and some remission of the neurological changes; and it seems clear that the changes in the nerve-cells are part of the pernicious-anæmia syndrome. SAMSON and his co-workers³ have investigated the changes in cerebral function associated with clinical pernicious anæmia and noted a significant diminution in awareness, accompanied by electro-encephalographic abnormalities. These changes, too, are completely relieved by treatment with vitamin B₁₂ (such improvement precedes changes in the blood-count), and this they attribute to the effect of vitamin B₁₂ on cerebral metabolism.

The well-known glossitis of pernicious anæmia is also apparently a symptom of metabolic disturbance, this time in the epithelial tissues. It too can be controlled by vitamin B₁₂; but the action may not always be direct, since BROWN,⁴ in Glasgow, showed that other single members of the B-vitamin complex, such as pantothenic acid or nicotinic acid, were effective by themselves.

GRAHAM and RHEAULT⁵ now report changes in epithelial cells in patients with pernicious anæmia. In their laboratory cytological examination of gastric contents has revealed two types of cell. The majority are squamous epithelial cells from the upper respiratory tract and the œsophagus, most of which have been swallowed; they come from the superficial layer of the squamous epithelium. The other cells, which are fewer, are columnar epithelial cells from the gastric epithelium itself. In patients with untreated pernicious anæmia both these types show characteristic abnormalities. The squamous cells are considerably larger than usual; they sometimes have multiple nuclei as a result of abnormal mitosis; and the nuclear pattern, instead of being regular, is irregular with odd clumping of the chromatin. The gastric columnar cells are also larger than normal; and their nuclei show distinct increase of chromatin, which is irregularly distributed. When the patient is treated with vitamin B₁₂ these abnormal cell changes become less pronounced, and in full clinical remission they cannot be detected at all. No such abnormalities were found in patients with comparable hæmoglobin levels due to iron-deficiency anæmia or acute blood-loss; so anæmia alone is not the cause. Nor do GRAHAM and RHEAULT think that the absence of free hydrochloric acid in the stomach is responsible. Once again lack of vitamin B₁₂ seems to be the reason. It is noteworthy that in pernicious anæmia the cellular abnormalities—excessive size and distorted arrangement of chromatin in the nucleus—are similar in the epithelial and the hæmopoietic cells. What other cells, it may be asked, are likewise affected, and do the neurological changes follow cellular changes in the central nervous system? The mode of action of vitamin B₁₂ is not yet clear, but VILTER and co-workers⁶ and others have suggested that it is one of the essential components of the enzyme system concerned with the formation of nucleic acids. The blood-forming tissues are most severely affected because throughout life there is in them such a rapid turnover of cells. Both THORELL⁷ and J. N. DAVIDSON and co-workers⁸ have found that in pernicious anæmia erythroblasts tend to accumulate desoxyribonucleic acid in the nucleus, and ribonucleic acid in the cytoplasm, beyond the normal levels. The effect of vitamin B₁₂ on the growth of animals⁹ supports the view that it plays an important part in general cellular maintenance and multiplication. These nucleic-acid changes are engaging the attention of many investigators. Meanwhile it becomes clearer that megaloblastic anæmias are, as MALLARMÉ¹⁰ puts it, cytological dystrophies;

in pernicious anæmia absence of vitamin B₁₂ seems to be the cause, while in the megaloblastic anæmias of steatorrhœa and pregnancy folic-acid deficiency seems to be responsible.

All this new evidence makes it difficult to maintain the original idea that pernicious anæmia was due to a reversion of erythropoiesis to an embryonic form that produced red cells which could not stand up to the wear and tear of the adult circulation. It seems more likely that pernicious anæmia is a generalised disease of cell formation, and that the effect of lack of vitamin B₁₂ on cell size and nuclear pattern becomes manifest in erythroblasts after the pro-erythroblast stage, and in granulocytes after the myelocyte stage. It is fortunate that so simple a treatment as the exhibition of vitamin B₁₂ rectifies the multiple changes in this generalised disease.

Ureterocolic Anastomosis

DISSATISFACTION with the results of ureterocolic anastomosis has led to the development of new techniques. The pioneer methods of COFFEY¹ and STILES,² by which the ureter is led through the wall of the colon without direct anastomosis between the mucosæ of colon and ureter, have become less popular owing to their tendency to cause a stricture; this, though it may prevent reflux of gas or fœces up the ureter, interferes with drainage of the kidney, and hydronephrosis is very likely to develop. The direct techniques of NESBIT³ and CORDONNIER⁴ have the opposite disadvantage of often allowing reflux, and thus increasing the risk of renal infection. LEADBETTER⁵ has sought to combine the advantages of both methods by a direct mucosa-to-mucosa anastomosis, with a valvular arrangement fashioned by burying the lower end of the ureter in a tunnel formed by the wall of the colon. PYRAH⁶ reports that with this operation his own early results have been satisfactory.

Hardly any other abdominal operation gives rise to complications more commonly or in greater variety. Among the 1673 operations analysed by JACOBS and STIRLING⁷ the immediate-morbidity rate was over 40%. Partly, no doubt, this rate is so high because the operation is usually done for severe genito-urinary disease, very often in elderly patients; but even in young patients in good general condition complications are common. JACOBS and STIRLING find that these number no fewer than fifty-nine. Of the "non-specific" complications in the large series that they review, ileus developed in 114 (6.7%) cases; and they suggest that excessive preoperative preparation of the bowel may have helped to precipitate this disorder. Burst abdomen occurred in 41 (2.5%) cases; and probable factors here were abdominal distension due to ileus, or simple gaseous distension in a weakened patient. Intestinal obstruction may result from adhesions or from strangulation of a loop of bowel between the ureter and the posterior abdominal wall. Fistulæ (urinary or fœcal, or combined) occurred in 9% of cases, and renal complications (including infection, uræmia, and urinary calculi) in 5%. The most important late complication is electro-

lyte imbalance.⁸ As regards the clinical picture of this disturbance, nothing has been added to the description by FERRIS and ODEL⁹; and, despite much investigation, unanimity has not been reached on its cause. Most workers, including KEKWICK et al.,¹⁰ LAPIDES,¹¹ and CREEVY,¹² believe that impaired renal function is the most important factor, but ROSENBERG¹³ states: "the primary factor in the production of hyperchloræmic acidosis following uretero-sigmoidostomy is, in most cases, reabsorption of urinary constituents, primarily anions, from the large bowel." The experimental work of PARSONS and his colleagues^{14 15} at Leeds and of ANNIS and ALEXANDER¹⁶ has clearly shown that differential absorption of electrolytes takes place, chloride being absorbed in excess of sodium. PYRAH suggests that in cases of electrolyte imbalance with severe clinical symptoms the sequence of events is probably as follows: differential absorption of chlorides from the colon; renal infection leading to interference with the acid-base regulating mechanism of the kidney; excessive loss of base from the kidney and acidosis; progressive dehydration; nausea and vomiting leading to increased dehydration.

The treatment of electrolyte imbalance should be started in the immediate postoperative period. Continuous rectal drainage by an indwelling catheter should be maintained for seven days to prevent any rise in pressure at the site of the anastomosis, and to diminish the total amount of urine in the colon. Fluid balance must be carefully maintained, and the administration of electrolytes limited to the body's requirements. Sodium chloride must be given sparingly because of the differential absorption of chloride, and any sodium deficit must be met by giving sodium lactate as well as sodium chloride so that the final ratio of sodium to chloride is 1.4 to 1. When oral feeding is started a mixture containing 4 g. each of sodium and potassium bicarbonate is given every twenty-four hours. Fluid intake should be as great as is compatible with urinary output, to prevent renal infection; and any infection should be vigorously treated with a broad-spectrum antibiotic. PYRAH decides on the later treatment of electrolyte imbalance by the severity of the symptoms:

1. Patients who have no symptoms should be instructed to restrict the amount of sodium chloride in their diet, to take sodium bicarbonate 4 g. daily, and to micturate fairly often.
2. Patients with mild symptoms may be quickly relieved by reducing their sodium chloride intake and giving sodium bicarbonate 2-3 g. eight-hourly until the acidosis has been corrected.
3. Patients with severe symptoms, such as dehydration and nausea, should be treated in hospital under close laboratory control. The complex electrolyte disturbances require individual correction, but with rational treatment even apparently hopeless cases can be revived.

The many disadvantages of the operation have led to a search for alternative measures, and several

methods of constructing an artificial bladder have been devised.¹⁷ One of the minor disadvantages of an artificial bladder is the production of considerable quantities of mucus, which may lead to blocking of a catheter. GODFREY¹⁸ has found that preliminary irradiation of the ascending colon greatly reduces the secretion of mucus, and he suggests that it also diminishes the reabsorption of electrolytes. PYRAH describes a method of avoiding a ureterocolic anastomosis which may prove useful in some cases of contracted bladder. An isolated loop of lower ileum is prepared, one end is closed, and the other end is anastomosed to the solitary ureter. A wide side-to-side anastomosis is then made between the bladder and the ileal loop. This considerably increases the bladder storage capacity and relieves frequency of micturition.

By the development of such techniques, the conditions for which there is no alternative to ureterocolic anastomosis may be reduced in number. In PYRAH's⁶ words :

"The operation of ureterocolic anastomosis is not a procedure like appendicectomy for gangrenous appendicitis or cholecystectomy for gallstones, which finally removes from the patient a diseased organ which may be threatening life; it is rather a procedure which, by producing a fundamental change in the excretory arrangements of the body, often confers great benefits on the patient, but also carries risks of renal infection and derangement of the blood electrolytes that are sometimes inimical to health and occasionally dangerous to life. It is reasonable, therefore, that . . . attempts should be made to relieve the pathological process for which it is performed by some alternative procedure."

The A.R.D. Virus?

SOMEWHERE in the no-man's-land between epidemic influenza and the common cold lies a group of febrile upper respiratory infections which are not normally epidemic. In 1938 STUART-HARRIS, ANDREWES, and SMITH¹⁹ described a syndrome which was more insidious in onset, and was more usually accompanied by sore throat and cough, than infection with influenza-A virus. This syndrome was named "febrile catarrh" to indicate the catarrhal manifestations—obstructed nose, hoarse voice, signs of tonsillitis or pharyngitis, and exudation of mucous or mucopurulent secretion. Individual cases could not be separated from influenzal infections, but the two conditions were thought to be distinguishable in the mass. The U.S. Army Commission on Acute Respiratory Diseases²⁰ described a similar condition which they called "undifferentiated acute respiratory disease," or A.R.D.; and they also spoke of cases of atypical pneumonia and exudative pharyngitis, although it was not known whether these three conditions represented different clinical manifestations of the same aetiological agent. A.R.D. was particularly common among new entrants to the army—unlike influenza, which attacked new recruits and old stagers indiscriminately. The commission²¹ also investigated the aetiology of this disease in volunteers. In 12 out of 14 volunteers, a filtrate of nasopharyngeal secretions from a typical case produced a mildly febrile

respiratory illness five to six days after inoculation, and tests of immunity distinguished this infection from the common cold. These findings suggested that A.R.D., which is probably the same condition as "febrile catarrh," is a distinct entity with a rather longer incubation period than has been described for influenza and the common cold and is probably caused by a filtrable virus. The extent of A.R.D. in the general population is unknown, and this would be extremely difficult to assess without a laboratory test for the aetiological agent.

It is good news, therefore, that attempts to isolate an aetiological agent from an outbreak of A.R.D. at Fort Lennox Wood, Missouri, by inoculating tissue-cultures of HeLa cells (from a uterine carcinoma), have resulted in the recovery of a new virus. HILLEMAN and WERNER²² examined 29 throat washings and recovered 5 cytopathogenic agents, presumably viruses, from 3 cases diagnosed as primary atypical pneumonia and 2 diagnosed as A.R.D. Apart from its cytopathogenic action, the distinguishing features of the virus are not yet known; but serological tests by neutralisation of the virus's cytopathogenic action, and complement-fixation tests, have yielded important results. Each of 7 cases of primary atypical pneumonia and 6 of 7 cases of A.R.D. from this outbreak showed a fourfold or greater rise in antibody to the new virus. No rise in antibody to this virus was found in sera from patients with influenza A or B, psittacosis, ornithosis, or Q fever, or in 3 cases diagnosed as primary atypical pneumonia in which there were significant increases in cold or streptococcus MG agglutinins. The results suggest that the new virus may be a cause of some cases of A.R.D. or primary atypical pneumonia. HILLEMAN and WERNER mention that the agent they describe has proved to be immunologically related to a virus recovered earlier by ROWE et al.²³ from cultures of adenoid tissue. These workers noted that during long in-vitro cultivation of adenoids obtained at operation on young children many of the cells showed a characteristic rounding, progressing to complete destruction of the epithelium. Transfer of these cultures to HeLa cells resulted in identical changes in the recipient cells; and the causative agent, which was filtrable, has been called the "adenoid-degenerating" or A.D. agent. It is important to find out whether the A.R.D. and A.D. agents are the same or are simply members of the same family. Possibly the upper respiratory passages harbour a group of related viruses (cf. the pneumococci) of which some members are latent and harmless commensals while others can cause A.R.D. or primary atypical pneumonia. Alternatively this virus may be of no aetiological significance in A.R.D. but may multiply when the ground has been prepared by the A.R.D. virus. This does not seem very likely, but the recovery of Coxsackie and poliomyelitis viruses from the same patients should warn us against jumping too readily to conclusions. It will be of great interest to see what the new virus and the A.D. virus do to the long-suffering volunteer who is prepared to risk febrile catarrh and possibly degeneration of his adenoids.

Annotations

PROSPECTS IN THE CIVIL SERVICE

THE long deadlock over the salaries of Civil Service doctors has at last been broken, on the terms which we publish on p. 878. The commencing salary of a medical officer (at the age of 35) is to be £1500, and the maximum salary in this basic grade will be £2100, which is a substantial advance on the present scale of £1250-1725. The Treasury would like the new scale to be permanent, but the committee which represents Civil Service doctors does not accept it as adequate and will be putting its arguments before the Royal Commission on the Civil Service, of which Sir Raymond Priestley is chairman. Increases of £100 and £50 are also made in the salaries of senior medical officers and principal medical officers; but these are regarded by all parties as no more than a token, and the Royal Commission will be asked to consider what the appropriate salaries should be. In the medical Civil Service as elsewhere, outstanding merit should bring commensurate reward, and responsibility should have pecuniary recognition.

The new scales operate retrospectively from Jan. 1, 1952; and this is only proper, for their negotiation has a long and not a happy history. As far back as 1948 the Institution of Professional Civil Servants asked that the recommendations of the two medical Spens reports should be applied to Civil Service medical officers; to which the Treasury replied that Spens was not applicable. In conjunction with the Ministry of Health Medical Staff Association and the B.M.A., the institution then formed a Civil Service Medical Officers' Joint Committee, which in August, 1949, presented a salary claim based on the two reports. After rejecting this in February, 1950, the Chancellor of the Exchequer said that he would appoint a committee to consider the remuneration, structure, and organisation of the medical Civil Service; and in the autumn of 1951 the Government accepted the recommendations of the Howitt Committee which had been charged with this task. But neither the constitution nor the conclusions of the Howitt Committee were acceptable to the profession,¹ which did not feel that the problem had had the full and judicial examination it deserved. The British Medical Association declined to accept further advertisements for Civil Service medical appointments; and, in associating ourselves with a request for fuller and more objective consideration of the subject, we said that "in the (perhaps unlikely) event of advertisements being submitted, we intend to add to each of them an indication to possible applicants that conditions of remuneration and promotion for doctors in the Civil Service have not yet been satisfactorily settled."² With this rupture the difficulty of obtaining good medical officers became even greater.

In the further study of recruitment for the medical Civil Service which the Royal Commission will no doubt undertake, we hope that emphasis will be placed as much on prospects of promotion as on the level of remuneration in the basic grade. In some departments there are few senior posts and the prospects for an able man are poor—a situation recognised by the Howitt Committee when it suggested that a doctor with exceptional qualifications, bearing responsibilities heavier than those usually falling on officers of his grade, should (with Treasury sanction) be allowed personal promotion. Commenting on this, we said: "Our impression is that, unless this loophole is greatly enlarged, the service, on the proposed salary scales, is unlikely to secure first-rate specialist members in the future."¹ This remains true; yet it seems to be nobody's business to see that the loophole is made into something more useful.

PENICILLIN BY MOUTH

SINCE penicillin first became available in quantity many attempts have been made to find a reliable method of administering it by mouth, and many vehicles have been suggested for this purpose. The relative instability of penicillin in acid solution, and the low blood levels following its oral administration, led to the belief that acid in the stomach destroyed much of each dose. Preparations in alkaline or buffered solutions, or in enteric-coated capsules designed to dissolve after passage through the stomach, were therefore investigated in an attempt to prevent such destruction; but no method has given constant and reproducible results. In all the earlier investigations high serum concentrations were attained in some patients, while in others penicillin could not be detected in the blood, whatever buffers or capsules were used as the vehicles.

The explanation now generally accepted for this unpredictability is that the power to absorb the drug from the intestine varies widely between different people, and that destruction by gastric acid is of minor importance. The capacity to absorb penicillin can be assessed only by trial and error, which is usually impracticable; so clearly progress in this field can come only from the development of compounds that are uniformly and reliably absorbed by all patients. This property has been claimed for N : N'-dibenzylethylenediamine penicillin (benzathine penicillin), though the inconsistencies in the reported trials suggest that the requirements may not be completely satisfied.¹⁻⁴ Elsewhere in this issue we include two further reports on benzathine penicillin. Dr. Fairbrother and Dr. Daber have compared its value with that of potassium penicillin, mainly in adults; while Dr. Beasley and Dr. MacPherson have investigated the absorption of benzathine penicillin in children of various weights.

The outstanding conclusion to be drawn from Fairbrother and Daber's report is that the absorption of benzathine penicillin from the intestine is no more constant or reliable than that of the potassium salt. In fact the results suggest that potassium penicillin is possibly the more satisfactory compound. In only 1 of 35 patients to whom 600,000 units of potassium penicillin was given by mouth was no penicillin detected in the blood four to six hours later. In a further 8 patients the blood level at this time was only 0.03 unit per ml.; this is often regarded as the minimum therapeutic level, though, as Fairbrother and Daber point out, it may often be clinically ineffective. Among 59 adult patients, four to six hours after administration of 600,000 units of benzathine penicillin no penicillin was detectable in 11 instances, and only 0.03 unit per ml. was found in another 11. Thus blood levels exceeding 0.03 unit per ml. four to six hours after the dose were observed in 74% of patients receiving potassium penicillin and in 62% of patients receiving benzathine penicillin. The absorption of benzathine penicillin by 31 children seemed more satisfactory in that no instances were encountered in which penicillin was undetectable in the blood. The interpretation of these findings is difficult, however, since the ages and weights of the children are not specified, and no comparable study of potassium penicillin is reported.

The importance of weight in relation to dosage is clearly seen from the report by Dr. Beasley and Dr. MacPherson, who have determined for children of various sizes the doses of benzathine penicillin required to give 0.03 unit per ml. in the blood after four, six, and eight

hours. No parallel study of other types of penicillin was made; but the large size of the doses required to ensure absorption, even in quite small children, suggests that benzathine penicillin cannot be greatly superior to the potassium salt.

These reports focus attention once more on the practicability of oral administration of penicillin. Repeated injections are always inconvenient in general practice, and in children they should be avoided if possible. Possibly, too, the incidence of sensitivity reactions might be diminished by oral administration. Nevertheless, the attainment of an effective concentration at the site of the infection has priority over these considerations; and, as Fairbrother and Daber point out, a single daily injection of 400,000 units of procaine penicillin costs less and gives more uniform results than 600,000 units of penicillin by mouth every six hours. For severe infections the administration of penicillin by mouth in any form seems clearly to be unjustified unless the antibiotic is also given parenterally in the early stages. In all other cases, before resorting to administration by mouth on the ground of convenience very careful consideration should be given to such factors as the sensitivity of the infecting organism, the danger of encouraging resistant organisms by inadequate dosage, and the severity of the infection.

CORTICOTROPHIN AND ADRENAL HORMONE IN URINE

MUCH of our knowledge of metabolism is derived from the analysis of urine. Although this gives only indirect information about what is going on inside the body there are advantages in using such material, which the patient can provide without hardship and which is in some ways more pure than the body-fluids themselves.

Rubin et al.¹ have recently demonstrated corticotrophin-like activity in the urine of some normal persons by injecting the urine into hypophysectomised rats and measuring the fall in the ascorbic acid content of the rats' adrenals. The urine of one patient with Cushing's syndrome possibly had a greater effect than normal urine. On the other hand Rubin et al. did not find any increase in the activity of urine from children with rheumatic fever who were receiving corticotrophin. The significance of these findings is not yet clear.

The effect of corticotrophin on the excretion of adrenocortical hormone is a fruitful field for research. The adrenal steroids in urine have been measured chemically and by biological assay, and certain derivatives without biological activity can be demonstrated after hydrolysis with glucuronidase. Cope and Hurlock² have applied the method of paper partition chromatography to the separation of cortical steroids in human urine. They have distinguished hydrocortisone (compound F) and cortisone, and two important steroid metabolites—tetrahydro-compound F and tetrahydrocortisone. The tetrahydro-compounds do not possess hormonal activity and may represent breakdown products of hydrocortisone and cortisone. The excretion-rates of all four compounds increased with administration of corticotrophin and after a major operation. Tetrahydrocortisone was usually present in greater amounts than tetrahydro-compound F, but the excretion of hydrocortisone often exceeded that of cortisone. All the compounds were much reduced in patients with hypopituitarism. When these patients were given cortisone, the excretion of cortisone and also of hydrocortisone and of the two tetrahydro-compounds increased. This suggests that cortisone is converted to hydrocortisone in the body, and that the adrenals do not necessarily play a part in the conversion. Evidence is accumulating that hydrocortisone may be the active

"sugar hormone" of the adrenal cortex; and this would explain, for instance, why hydrocortisone is more effective than cortisone when injected into rheumatic joints.³

MICROGYRIA

MICROGYRIA is a manifestation of severe dysplasia of the cerebral or cerebellar cortex, in which the convolutions are not only reduced in depth but also seemingly increased in number. It has to be distinguished from ulegyria, which is a thinning of the gyri due to scarring acquired after birth and often as a result of it; and to make the distinction clearer it is sometimes called polymicrogyria. It may be seen in the cerebrum or cerebellum of mental defectives and even in those of more normal mentality, while its association with other congenital anomalies, both in the brain and elsewhere, is well known: Norman⁴ noted the condition in 8 out of 45 cases of cerebral palsy. The convolutions are often rather wide, and their surface is finely wrinkled—an appearance that has been likened to a chestnut kernel. The abnormality, however, may be confined to the deeper convolutions, as Obersteiner showed in 1902, and may not be visible on the surface. A brain with microgyria involving many convolutions may be unduly small,⁵ but this association with micrencephaly is by no means invariable. The cortical architectonics vary considerably, but not infrequently they conform to a pattern in which there are four instead of the usual six layers of cells, with a conspicuous fibre lamina dividing them up into two main layers. The junction between the normal and the pathological may be abrupt.

Bielschowsky⁶ explained the anomaly as a failure of the neuroblasts migrating from the matrix to reach the periphery. One would thus expect the condition to be bilateral, but it was unilateral in 2 of the 6 cases, unassociated with porencephaly, reported by Norman.⁴ Ulegyria, too, may be bilateral, usually in the neighbourhood of the sagittal sinus; on the other hand, it tends to affect small areas of the cortex, to be sharply defined, and to be especially severe in the depths of sulci.⁷ Hallervorden⁸ thought that this characteristic deep-seated position was the result of severe congestion during birth. Clearly, therefore, it may be difficult to distinguish ulegyria from polymicrogyria. Doubtless many cases of ulegyria have, in the past, been regarded as examples of true microgyria, and this confusion is likely to continue in the future. Referring to brains which show structural anomalies at an early age, Norman⁴ remarks: "In the absence of clear-cut signs of malformation pathological criteria alone are usually insufficient to allow one to determine with confidence whether the damage to the brain has occurred during the later stage of pregnancy, during birth, or in early infancy"; and Malamud⁹ has arrived at the same conclusion. It would seem, therefore, that ulegyria tends to be labelled microgyria (or polymicrogyria) more often than the converse.

Of 3 cases of microgyria reported by Crome,¹⁰ instrumental deliveries are mentioned in 2 but in the third no clear history was available. One child, who died at the age of 12, had been retarded from birth and had been epileptic from the age of 18 months; a dissimilar twin was normal. The other 2 children survived until the ages of 7½ and almost 2. In all 3 brains the microgyria was associated with micrencephaly

and compensatory hydrocephalus, and in 2 of them there was paraventricular calcification, so that radiologically some confusion might arise in distinguishing this disease from tuberous sclerosis or even toxoplasmosis. Crome noted that the microgyria was usually more extensive than it first seemed, for when the sulci were examined closely cryptomicrogyria was often found. His third case was associated with arhinencephaly and porencephaly, but the microgyria was restricted in each hemisphere to an area around the Sylvian fissure. He concluded that there must have been defective development of the brain, and the symmetrical distribution supported this view; but the covering membrane over the porencephalic cyst showed histological evidence of the destruction of existing brain tissue, so the defective development might itself have been the result of a destructive lesion during early development. This deduction is in keeping with the view of Cohen and Neumann¹¹ who believe that vascular occlusion early in foetal life will cause maldevelopment or even agenesis.

When microgyria is associated with porencephaly the question arises whether the second condition is strictly a complication of the first—the result, for instance, of a secondary vascular softening—or whether the disturbance of the foetal brain which gives rise to porencephaly also causes microgyria in the adjoining cortex. Yakovlev and Wadsworth,¹² in their extensive studies, divide the porencephalies into the schizencephalies—"a manifest disorder of tectogenesis"—and the encephaloclastic porencephalies, but they do not seem to exclude the possibility of mixed forms. In one of their cases lesions of three different ages were found; one of them probably dated from birth, and the other two were earlier, thus illustrating, they suggest, a sequence of superimposed events brought about by a chain of largely obscure causes "in which the circulatory disturbances and the destructive encephalomalacic lesions represent an incidental and fortuitous factor." If the cause of porencephaly is complex, the same can be expected of microgyria, which it so often accompanies. Provided, however, that there is no question of delay in the migration of neuroblasts to the cortex, the disturbance of the foetal brain that produces true microgyria would be expected during the fourth or fifth month—the time when migration normally takes place.

Hydrocephalus, it seems, may also be looked for in association with microgyria. Crome described it in each of his 3 cases, but Norman found it in only 2 out of 6 cases, and in both of these the cortical defect was bilateral. Of particular interest in this respect is a case described by Hallervorden.¹³ A married woman in the fifth month of pregnancy made an unsuccessful attempt to commit suicide with coal gas. The baby was born at the expected time, but failed to develop normally and later suffered from athetosis. The head was retracted and there was severe lordosis of the lumbar spine. The child died at the age of 1. True microgyria was present in parts of both frontal lobes; and microscopically there was widespread loss of nerve-cells in the third layer of the cerebral cortex. Both putamina showed cavitation and scarring, and so did the lateral thalamic nuclei on the right side. The brain thus showed what was apparently a prenatal malformation dating from about the fifth month of foetal life, and in addition there was evidence of gross softening of the basal ganglia and other vascular lesions. The possible part played by anoxia in microgyria is referred to by Meyer and Cook,¹⁴ who found gliosis in the white matter of mental defectives, including those with microgyria; but they pointed out that defective tissue oxygenation

is often merely a final common pathway of aetiological distinct disease processes.

There is clearly much to learn about the cause of microgyria. A history of trauma at and after birth in defectives is hard to elicit, and it is known that serious birth injury may take place in apparently normal labour¹⁵; but reliable evidence of intra-uterine events likely to cause encephaloclasia or otherwise disturb the development of the nervous system is impossible to obtain.

THE DRAUGHT REFLEX

THOSE in charge of the management of lactation need to understand the draught reflex. The mother finds description elusive, and exact recording sometimes takes part in the conditioned reflexes which set it off. The mere act of thinking of the reflex may bring it into action before its proper time. Yet the doctor or midwife depends largely on subjective accounts since there is little objective evidence by which to detect vagaries of the reflex that may be producing feeding difficulties.

Dr. Isbister¹⁶ has sought to analyse the usual behaviour of the reflex and some of its variations by questioning many mothers as well as making observations on herself. She confirms Waller's¹⁷ finding that most primiparæ feel the reflex for the first time only after about three weeks, whereas multiparæ may feel it even before delivery; and she confirms, too, that nearly all successful feeders experience it. Many of the mothers questioned had noted that sometimes the draught was delayed and seemed to last less long than usual—particularly when they had been suffering embarrassment, fatigue, or worry. Anger roused just before feeding delayed the draught by two minutes. Dr. Isbister suggests that too vigorous action of the reflex may in some instances be responsible for wind, colic, vomiting, and frequent stools in the baby; and, to avoid this difficulty, she recommends evoking the reflex before the feed by expressing a little milk. Like Waller, she believes that gastrointestinal symptoms in the infant may be due to gulping large quantities of milk; but perhaps they may sometimes be the outcome of maternal fear transmitted humorally in the milk. The mother's fear of suffocating her baby may be great, and assurances that the baby can manage the situation if given his head are often as effective as any other remedy for the baby's disturbances.

HALF-WAY HOUSE

ON March 31 an important experiment was set in train at Liverpool when Sir Henry Cohen and the Bishop of Liverpool opened a hostel administered by the Liverpool Personal Service Society. The regional hospital board has contracted for the use of 18 of the beds by patients transferred from hospital who are not yet fit to return home. The remaining 20 beds are available to the local health authority for patients who are aged and frail but who do not require medical and nursing care. Experience with this hostel may answer some of the questions concerning borderline cases that are neither fully the responsibility of the hospital service nor fit enough for the type of hostel provided by the local health authority under the National Assistance Act. The progress of this experiment will be keenly watched not only by the administrators of these two branches but also by general practitioners, who are in a good position to see the ill effects of the hiatus that the new hostel is designed to fill.

ON April 12 Sir RUSSELL BRAIN was re-elected president of the Royal College of Physicians of London for the ensuing year.

Reconstruction

A DIAGNOSTIC CENTRE

THE Nuffield Diagnostic Centre at Corby in Northamptonshire is being opened on April 23 by Lord Nuffield. The centre has been sponsored by the Nuffield Provincial Hospitals Trust and the Oxford Regional Hospital Board, and it has been designed as part of a plan to meet the medical needs of the rapidly growing town of Corby.

The Plan for Corby

In 1934 Corby was a village with a population of about 1500. Messrs. Stewarts & Lloyds then opened the first part of the steelworks there; the industry has been expanding ever since, and Corby has grown with it. In 1950 a development corporation was established, under the terms of the New Towns Act, to help the urban district council in their work of development. The steel industry is to be further enlarged, and light industries will, it is hoped, increase too. The aim is a town of 40,000; and one of the corporation's main tasks was the provision of a town centre, and this is now well under way. Close to the town centre there is a large area of woodland, and it is here that the diagnostic centre has been built; and an adjoining site has been reserved for the hospital and clinic buildings that may be added later.

In 1949 the Nuffield Provincial Hospitals Trust examined the medical needs and opportunities of Corby, and the result was the formation of a committee which was asked to draw up a plan to meet these needs. The committee included representatives of the Trust, the Oxford Regional Hospital Board, the Northamptonshire County Council, the Northamptonshire Executive Council, the Corby Urban District Council, and Stewarts & Lloyds. It was clear that no new hospital could be built for a long time, yet something had to be done to meet the difficulties of the general practitioners, who had no convenient means of investigation or consultation for their patients. As things were, they had to refer them to Kettering (8 miles away) or Northampton (25 miles);

and this meant much inconvenience and loss of time for the people of Corby, and much extra work for the nearest hospital, at Kettering. So the Trust proposed to all concerned that there should be set up

“a diagnostic centre, which will include examination and treatment rooms to be used by the general practitioners, and also by the hospital service as a consultant outpatient department; chest clinic, and X-ray and physiotherapy departments; and a dental suite.”

And this centre forms the first stage in the plan for Corby. (For the time being, at the suggestion of the Ministry of Health, the dental suite has been omitted.) Later, a maternity unit will be added by the regional board, and there may also be a unit of general-practitioner beds. The existing local-authority clinics in the area are at present sufficient, but when extra clinics are needed they will be built beside the diagnostic centre.

The hopes are that this scheme will not only enable the Corby doctors to provide a better service for their patients but also lessen the burden on Kettering General Hospital and other hospitals in the district.

The Design

The centre has been designed by Mr. R. Llewelyn Davies, A.R.I.B.A., the director and architect of the Trust's Investigation into the Functions and Design of Hospitals; and he has had the help of Messrs. Gotch, Saunders, & Surridge, architects, of Kettering. One purpose of the experiment was to show that the essentials for a diagnostic centre of this kind could be provided at a reasonable cost. The contract price for the building was rather less than £34,400, and the cost of furnishing and equipping it was about £13,000; and this is certainly modest by health-centre standards. The contract price works out at a few pence over £3 10s. per sq. ft. of floor space; the permitted expenditure on private houses is usually around £2 per sq. ft., but the architect clearly has a lot more to do in each square foot in a diagnostic centre than in an ordinary house. And Mr. Llewelyn Davies and his colleagues have done very well in building an efficient and pleasant building for such a sum.

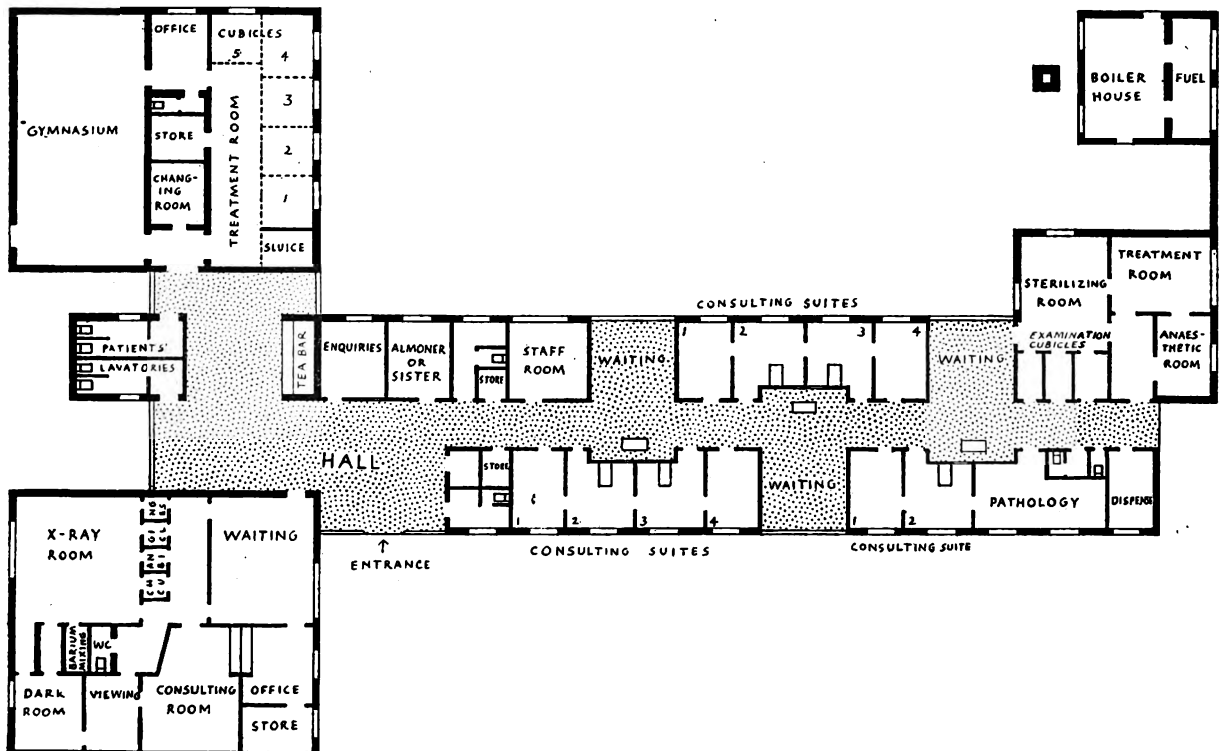

Fig. 1—Plan of the diagnostic centre.

The three parts of the building—the consulting and treatment wing, the physiotherapy department, and the combined chest clinic and X-ray department—are neatly arranged around a central entrance hall and reception desk (fig. 1). Waiting-spaces, rather than waiting-rooms, have been fitted into the design, and there are splendid wall-high windows to light them (fig. 2). The consulting-rooms, which will be used by both G.P.s and consultants, have examination rooms alongside, and one of the consulting-rooms is equipped for the ophthalmologist. They all have 'Anglepoise' lamps and viewing-boxes fitted to the walls.

The compact and well-provided pathological laboratory is down the same corridor; and further on there are the treatment rooms. Three small cubicles are equipped for dealing with patients who have dressings to be changed, and the small treatment room and anaesthetics room will enable the doctors to undertake many more minor operations than they could hope to do in their surgeries.

The physiotherapy block includes a remarkably roomy gymnasium (fig. 3) with plenty of things to keep the patients hard at it. The department can take on anything that a bigger hospital one can do; the only limitation is its size and the physiotherapist's one pair of hands. It remains to be seen how great will be the call on his services and those of the specialist in physical medicine: they could be the busiest people in the place.

The X-ray department is superbly equipped; the tilting table will be the envy of visiting radiologists. Again, it is difficult to say straight away how much work there will be for the radiographer, but there is no doubt that it will be well done. If the planners have been lavish anywhere in the centre, it is here. No serious casualties will be brought to the centre for X-ray examination, because there are at present no beds to receive them or resident medical staff to attend them. But this may come later.

To keep the bills down, the architects have had to be pretty strict in their choice of materials. They have used plenty of glass to give a cheerful exterior—always difficult to achieve in a single-storey building. And they have chosen a pale sandy-coloured brick of pleasant texture which does not, as the yellowy bricks often do, emphasise the virtues of the reds. Internal walls in corridors and waiting-spaces have been left unplastered; and on these walls bold colour washes have been used to distinguish one part of the building from another.

The Working of the Centre

The centre does not qualify to be called a "health centre" under the definition of the N.H.S. Act of 1946, for it does not include all the facilities laid down in the Act. Moreover, it is not provided by a local health authority, and the G.P.s will not work in it as a group. The doctors will continue to use their own surgeries in Corby; but when they see a patient who needs a more thorough examination and investigation than they have the time or means to undertake immediately, they will arrange to see him later at the centre, where the G.P.s will rent some of the consulting-rooms. There they will be able to deal with the case more effectively

Fig. 3—The gymnasium in the physiotherapy department.

than they can usually do during busy surgery hours. The X-ray department and pathological laboratory will be to hand, and they will be able to consult colleagues who are using the centre in the same way or arrange for an opinion from one of the consultants who visit the centre for specialist clinics. If he is able to be there when the consultant sees his patient, the G.P. (and the consultant) will have the added advantage of direct contact; and, indeed, it is hoped that direct consultation between G.P. and consultant will be one of the most useful features of the new centre. To encourage this side of things, arrangements have been made for G.P.s to become clinical assistants to the consultants visiting the centre.

The Authorities Concerned

The *Oxford Regional Board* is providing and staffing the chest clinic and the X-ray and physiotherapy departments, and the board will pay a fee for the use of the consulting-rooms by its consultants and specialists. At the start, the clinics to be held at the centre will be: medical, surgical, obstetric, and gynaecological, paediatric, chest diseases, physical medicine, psychiatric, ear, nose, and throat, radiological, dermatological, ophthalmological, and orthopaedic. The pathological laboratory, the X-ray department, and the physiotherapy department will be under the direction of the corresponding consultant at Kettering.

At the end of the five-year experimental period, the *Northamptonshire County Council* will have the opportunity of buying the Trust's share in the centre. Meanwhile, the council is contributing £100 a year towards the maintenance expenses; and it will pay for any accommodation that may be needed when its existing clinics are unable to cope with the growing population.

The *Corby Urban District Council* has no statutory place in the affairs of the centre, but it is paying the rent of two cottages for the resident staff and is also meeting the cost of the laying-down and the upkeep of the lawns and flower-beds.

The *Corby Development Corporation* is providing a house for a physiotherapist.

Stewarts & Lloyds will contribute to the running costs of the centre during the early years of the experiment.

The capital for building and equipping the consulting and minor-treatment rooms and the pathological laboratory has come from the *Nuffield Provincial Hospitals Trust*, which is also helping with the initial running costs. The *Nuffield Health and Social Services Fund* has transacted much of the business for the

Fig. 2—A view of the centre showing one of the large windows.

Trust, and the ultimate control and coördination of the centre has been vested in the Fund. The Fund has sold part of the site to the regional board, and it is keeping another 5 acres ready for the board to build the maternity and G.P. units.

Administration and Staff

The day-to-day running of the centre is in the hands of a local management committee, appointed by the Fund. The Kettering and District Hospital Management Committee is responsible to the regional board for its part of the centre, but by a happy arrangement the house committee chosen to look after this part of the centre is man-for-man the same as that appointed by the Fund for the Trust's side of things. The group secretary of the Kettering committee is administrator in charge of the centre. The staff, at any rate for the time being, is a sister, staff nurse, assistant nurse, physio-therapist, radiographer, laboratory technician, almoner, receptionist, and 2 typists. Stewarts & Lloyds have also offered the help of their social relations officer.

The Value of the Experiment

Whatever the differences between a "diagnostic centre" and a "health centre," it is certain that progress at Corby will be judged partly in relation to the health-centre experiments that are under way in various parts of the country. In the matter of cost, the Corby centre is dearer than the centres at Harlow,¹ Bristol,² and Nottingham³ (where no attempt was made to provide special methods of investigation), and inexpensive by the standards of Woodberry Down⁴ and Sighthill.⁵ But, in counting the cost, the important point is that something was urgently needed at Corby: a hospital was out of the question, and the Nuffield centre was a likely answer. The particular interest of the experiment lies in the possibility that it will turn out to be an answer applicable in other districts where populations are large and hospitals small or far away.

To enable them to keep a close watch on developments, the Trust organised, in the late summer of 1953, a survey of the domestic, social, and economic difficulties that arose from the lack of a hospital and outpatient department in Corby. A year or two from now the same details will be re-examined, and it will then be possible to make a preliminary judgment of what the centre has done for the people of Corby. It will also be interesting to know what weight of work it has taken off the back of Kettering Hospital and other hospitals. There will be less doubt of the advantages to the general practitioners, who will have a splendid surgery-from-home, as well as an opportunity to draw added help from the consultant service and, indeed, to take part in it.

Medicine and the Law

Spinal Anæsthesia

THE decision in *Woolley and Roe v. Ministry of Health and others*,⁶ which we announced briefly last week, may not only mystify the layman but also leave the lawyers in some uncertainty.

The two plaintiffs, after undergoing minor operations in the Chesterfield and North Derbyshire Royal Hospital, became permanently paralysed from the waist downwards. 'Nupercaine,' supplied in glass ampoules, had been administered as a spinal anæsthetic, and at the trial Mr. Justice McNair found that injuries were caused by phenol percolating through invisible cracks into the ampoules from the solution in which they had been immersed. The layman may be surprised that patients could be refused compensation when so grave and apparently inexcusable an injury could happen to them in hospital. The lawyers may feel puzzled because, although the trial judge decided that the facts did not

speak for themselves (thereby establishing a prima-facie case of negligence), Lord Justice Denning now holds the contrary view. The hospital authorities in his opinion were responsible for the whole of the staff; he did not think that the hospital authorities and the anæsthetist could both avoid an explanation by each throwing the responsibility on the other. Lord Justice Somervell was prepared to regard the visiting anæsthetist as part of the permanent staff of the hospital, like the orthopædic surgeon in *Cassidy v. Ministry of Health* in the case which he helped to decide in 1951. The visiting anæsthetist, he said, was (like the orthopædic surgeon) a qualified skilled man, controlling as such his own methods. "The position of surgeons and others under the National Health Act will have to be decided when it arises, the position of hospitals under that Act may or may not be different from that of voluntary or municipal hospitals." We must wait, it appears, for further expensive litigation in order to find out how the law stands.

In the recent appeals the trial judge had found that phenol could find its way into an ampoule of nupercaine, stored in a phenol solution, through cracks undiscoverable by ordinary visual or tactile examination. The anæsthetist had not appreciated this risk, but, judged by the standard of medical knowledge to be imputed to competent anæsthetists in the year 1947, the anæsthetist was not negligent in failing to appreciate the risk; a fortiori the theatre staff were not negligent. The Court of Appeal accepted and adopted this view; and so, however sympathetic everyone must feel to the plaintiffs, the claim for damages failed. In Lord Justice Denning's words which we have already quoted, "we must not condemn as negligence that which is only a misadventure."

Injury during Removal of Plaster

In Sunderland County Court,⁷ a 65-year-old man was recently awarded £60 damages for a 14-inch cut inflicted by the shears when a male staff-nurse removed a plaster cast from his leg. The man had to have 28 stitches in his leg and was kept in hospital another three weeks. In his evidence, the senior orthopædic surgeon at the hospital described the staff-nurse, who had won a merit award since the accident, as an extremely conscientious worker, and he thought he had been unfortunate in dealing with a patient who did not say he was being cut; there must have been some diminution of sensation. Lord Uvedale, resident surgeon at Manor House Hospital, to which the patient was subsequently admitted, said he had never before seen such an injury from plaster removal.

The judge said it was not a case in which the hospital had to be punished for injuring the patient, but a matter of compensation. He had come to the conclusion that the patient had not felt the pain normally and that the sensitivity of the skin was diminished because the plaster had been on for 6 months. The staff-nurse had not carried out the removal with his customary skill.

Death from Anti-tetanus Serum

A verdict of misadventure was returned at an inquest at Southwark⁸ on a girl machinist who had died soon after a small test injection of anti-tetanus serum. She had run a needle into a finger at work and it became infected. When she attended St. Olave's Hospital, Rotherhithe, the surgeon ordered her to have anti-tetanus serum, and in preparation for this a test dose was injected by a nurse into the girl's leg. She became unconscious, had convulsions, and died despite artificial respiration and injection of "heart stimulants." Dr. F. E. Camps, the Home Office pathologist, said that a section cut through the injection site showed that the needle had entered a small vein so that the serum was injected straight into the blood-stream.

DIFFERENTIAL DIAGNOSIS

AN APPARATUS TO ASSIST THE LOGICAL FACULTIES

F. A. NASH
M.R.C.S.

MEDICAL DIRECTOR, SOUTH WEST LONDON MASS X-RAY SERVICE

THERE are at least three ways in which one learns medicine: from first-hand experience at the bedside, from spoken and written accounts by others of individual cases they have seen, and from written generalised accounts of many similar illnesses grouped into what we call diseases. The student has two tasks: he must learn the symptoms and signs of all the important diseases, and he may also try to learn all the diseases that cause each particular symptom. The former task is usually better done than the latter. To help him to learn about diseases he has the descriptions given in the "straight" textbooks, while to help him to learn (or look up) the diseases that cause particular symptoms there are books which give the differential diagnosis of separate main symptoms.

THE MECHANISM OF DIAGNOSIS

What happens in the doctor's mind when he is faced with a patient? This will depend on his experience, on his book knowledge, and on his mental endowment; but the diagnosis will be made in one or all of the following ways.

(1) The patient's story and the results of physical examination may bring into action the subconscious process of immediate recognition of the disease. The diagnosis here is made in the same way as we "diagnose" the identity of our friends—i.e., without conscious formulation of reasons but with a high degree of confidence and accuracy. This capacity for recognition diagnosis is the invaluable possession of the doctor who has had much experience in practice and has profited by it.

(2) The doctor may recall descriptions from books or from memories of practice of several diseases that might fit the patient's story. This process of recalling to consciousness the diseases that enter the differential diagnosis is not usually a logical effort but relies on the storehouse of the memory to "throw up" several likenesses to the present patient. That it is far from being the infallible result of an act of volition is suggested by the experience that more things are missed through not being thought of, and so not looked for, than through not being known. The doctor will try to hold in his mind's eye the descriptions of the diseases he has "thought" suitable for consideration in his differential diagnosis, and to see which best fits the patient's case as he has elicited it. In no case will his patient have *all* the described symptoms of any of the textbook diseases, because they are collective descriptions. The individual case presents usually but a tattered fragment of the full-blown composite picture of the disease described in the textbook.

This task of assessing the significance of all the patient's symptoms together and relating them to a disease is extremely difficult. Theoretically the doctor could go through the descriptions of diseases in his straight textbook—i.e., review it from cover to cover to find the description that most nearly fits his patient. But in practice one cannot re-read a textbook for each patient.

(3) The doctor may take a main or significant symptom or sign, and, using it as an intellectual straw to cling to, or start from, in a sea of memories and observations, he may review the diseases that could cause it. He may do this for several of the patient's symptoms in turn, perhaps using a book on the differential diagnosis of main symptoms to help him. If he uses a book like French's *Index* he will find his fingers in different pages on which are given lists of causes of those of his patient's symptoms he tries to look up. To find the disease names that occur every time under each separate symptom as shown in different parts of the book may be far from easy, even with pencil and paper to hand. To hold the several lists

of possible causes of each of the patient's different symptoms and signs in mind at once and logically to select those causes that best explain—i.e., are common to—the largest number of his symptoms is beyond the capacity of most minds.

However differential diagnosis is approached, our literary tools will not enable us to recall without fail all the diseases that could be the causes of the symptoms and signs, taken together, of each particular patient. The inadequacy of these tools is inherent in the structure of the *page* as the unit holder of data, owing to its rigidity—i.e., its inability to present the relevant data in the order or pattern that may be required. What is needed is a device which will answer the question "What are the possible causes of the group of symptoms and signs I have elicited from my patient?" Theoretically a giant table containing hundreds of vertical columns of symptoms and signs and hundreds of horizontal rows of diseases would suffice, but such a table would be as big as the wall of a room and far too unwieldy for practical use.

The reason why no such device has been found is that the only commonly used fact-holder has been the book or a card, both of which hold the facts as symbols on a page. The continuous use of the page for thousands of years makes it unnecessary to speak of its advantages for recording. Yet we may conceive that the book, and particularly its unit the page or card, may not be the ultimate form of record. Though some of the defects of the bound book are obviated by the loose-leaf ledger or card system, even cards have the limitations inherent in their structure. In narrative records side-by-side comparison of groups of data is impossible, and the table on a single page or folding sheet is a sign that a vague want is felt for devices to display any required relationships. Unfortunately if one makes a table big enough to include as much data as would occupy a whole book of narrative type, the thing becomes utterly unmanageable. For any particular problem we have in mind, the table is cluttered with irrelevant data that obscure the data and their relationships that we are trying to trace.

Apparatus

The solution offered here is a mechanical table with hundreds of removable columns which allow the manipulation at will of any chosen groups of qualitative data. It is a supplement to books and a mechanical aid to certain types of logical thinking.

The device consists of a frame to one side of which is fixed a category reference index. In the index the categories (in this instance diseases) are listed one beneath the other (in the prototype in alphabetical order). A space is provided in the frame into which fit a number (8 in the prototype) of detachable members of strip form which are inserted with their longitudinal axes parallel to the category reference index. Each detachable member carries a reference to the symptom or other attribute concerned—e.g., hæmoptysis—and on its exposed surface is graduated (or written on) at right angles to its longitudinal axis in all those places which (when the member is in position in the frame) align with a category (disease) in the index in which the symptom the strip represents is known to occur. There may be hundreds of detachable strip members which are conveniently stored in a separate index ready for use when wanted. They can each represent any chosen single attributes—e.g., symptoms, signs, age-incidence, and sex-incidence of diseases.

The prototype contains about 300 diseases. This list when typed is about 4 ft. 3 in. long. By photographic reduction this was made into a scale about 2 ft. 3 in. long. The scale can be reduced still more, so that the list of 300 diseases is only 18 in. long. The symptom members are made of obeche wood (*Triplochiton scleroxylon*). In the diagram the symptom members are numbered, but in practice it is preferable for the name of the symptom to be printed on each one.

To obtain classification of a number of attributes to a particular category or categories, the appropriate members are taken out of the store and inserted one beside the other in the frame. It will then be seen that each symptom has its own spectrum or pattern of causation. It will be also seen that in some places two or more of the spectral lines lie adjacently against the same disease, with the result that on the apparatus it looks as if a single straight horizontal line has been drawn across several or all of the symptom units opposite that disease. Our patient's disease must be one of these diseases that would account for all or most of his symptoms. These can be seen literally at a glance. One can also see at once which disease would explain some of his symptoms but not others. Roughly, the diseases with the longest horizontal composite lines against them will be those we should consider as possible diagnoses in our particular patient whose symptoms we earlier fitted into the machine. Such a preliminary review of the range of diagnostic possibilities and probabilities could precede and to some extent guide the physical examination and investigations. However, if desired, sign strips or units can be made on the same principles as the symptom strips and the whole case can be put into the machine for analysis and consideration. Although in the prototype the spectral lines have been used, it would be possible to use adjectives, figures, or other symbols instead—e.g., on the cough unit bar, instead of a simple linear spectrum,

one could have adjectives such as brassy, gander, and stridulous, in the appropriate places—i.e., opposite diseases to which they are applicable. It is intriguing to find how many causes the apparatus can suggest for one or two of a patient's symptoms or signs, and how, as more and more of the patient's symptoms are inserted, the range of possibilities rapidly narrows.

Discussion

What does the apparatus described do? It tells us what diseases could account for any particular group of symptoms we care to put into the machine. Its programme of symptoms and signs is potentially as great as the repertoire we decide to give it. A book will not arrange data in the way required for the solution of particular individual problems, and for this reason the man who merely knows the books by heart cannot apply the knowledge he has to particular problems. His associational ability to extract and associate information from different parts of the book is of a low order.

Limitations of Apparatus

The machine can only suggest which diseases a particular patient may have, and so give the doctor some jumping-off points in thought from which he can go on to consider the most likely diagnosis or what further observations he needs to help clarify the issue. The apparatus will also indicate some points against certain diagnoses that may have spontaneously occurred to the observer. It is not a substitute for any of the human faculties needed in the difficult art of differential diagnosis. All it can do is to assist, and so perhaps improve on, the workings of the unaided ordinary mind in certain parts only of the process of diagnosis. Any diagnostic aid, whether book, list, or other device, can never be the sort where one puts in a penny and out comes the diagnosis, because no apparatus will ever be able to take a proper history, examine the patient intelligently, and possess clinical judgment.

Logically the apparatus can be said to have the purpose of stating the inclusion or exclusion of classes in reference to one another, especially in demonstrating the relationships of overlapping classes. Thus, when we say "This patient has a cough" we could be considered logically to be saying "This patient is a member of the class of all coughers." The "class of all coughers" will be distributed among many groups of ill people who have the different diseases of which cough forms a part. Other classes of persons with other symptoms will overlap the class of all coughers in so far as they occur in the same diseases as cough. To put the matter more traditionally, the symptom strips represent grouped data about certain qualities, attributes, or characteristics of the diseases or other entities listed in the reference category index.

Summary

Books and card indexes have shortcomings inherent in their unit, which is the page. When we use them as fact-holders they impose on us rigidity in the arrangement of data.

A physical aid to thinking, which may be called the group fact manipulator or associator, is described.

The apparatus allows the free manipulation at will of prefabricated groups of data for the solution of classificatory problems in medicine and other subjects. If the symptoms of a particular patient are put into the device, it will indicate at a glance the range of differential diagnostic possibilities. It is a supplementary aid and in no way a substitute for books, knowledge, experience, or clinical judgment. Like any tool it can be misused; but time may give it a useful, though limited, place in teaching and practice.

REMPLOY

FROM A CORRESPONDENT

No other industrial concern has quite so curious a problem to solve as Remploy Ltd.; or is more exposed to political cross-fire. Cannon to right of them, cannon to left of them, fairly describes the situation. On the one hand are those who say that Remploy factories should be purely a social service for the severely disabled, giving them somewhere to work and to feel they are earning a living. On the other are those who think that the country cannot afford sentimental luxuries, that it is cheaper to support these men and women in idleness on public-assistance funds, and that anyhow with proper management Remploy factories could be made to pay their way.

If Remploy factories could in fact be made to pay their way, of course, most of their critics would be silenced. Most of them, however, run at a loss, anyhow on paper; and according to industrial experts they always will, though the degree of loss may be reduced in time. Partly because these severely disabled people tire easily, partly because they are more often away sick than healthy workers, and partly because it has not always been possible, so far, to keep them supplied with steady runs of work, they have not been able to achieve and maintain more than a third of the output of workers in ordinary industry. The overhead costs of running a factory, however, go on all the time, whether the employees are working fast, slowly, or not at all. That is the crude financial problem—though only one aspect of it. There are others, and there are many other sides to Remploy; so we should look more closely at what they are doing, what they have done already, and what they hope to do, before assessing even the financial loss or gain.

RAPID EXPANSION

Remploy Ltd. was formed in 1945, under the Disabled Persons (Employment) Act, 1944, as a public corporation financed by Treasury funds, to provide employment for people on section II of the Disabled Persons Register—that is, for people so severely disabled that they are unable to work under ordinary industrial conditions. It has thus no choice about the type of person it employs.

In the nine years since it was founded Remploy has opened 90 factories; indeed all 90 were in action within seven years of the start. It has been much criticised for forging ahead so fast, instead of proceeding more cautiously and learning by experience; but it had no choice. The pressure on it—from Ministries, local authorities, and the public—was so great that it was obliged to set up factories much faster than it wished, or thought advisable. Between March, 1949, and March, 1950, for instance, it set up 26 factories.

There are at present some 6000 people employed by Remploy. The number of disabled on section II of the register who were still unemployed in January, 1954, was 5592; so the factories have not yet absorbed all the available labour from their pool. Some of these disabled unemployed, however, are doubtless unemployable; some live too far from the factories; and some will not be fit for factory work, though they may be able to do work at home. Remploy has already begun to organise homework schemes on a small scale, and is so far employing 137 people in this way.

The disabilities of Remploy workers include those due to injuries and amputations, congenital malformations, arthritis, diseases of the digestive and genito-urinary systems, diseases of the heart, circulatory system, and lungs (including pulmonary tuberculosis), skin diseases, ear and eye defects, organic diseases of the nervous system (including epilepsy, disseminated sclerosis, and poliomyelitis), mental defect, neurosis and psychoneurosis, and many others.

The average age of the workers is high compared with that of workers in ordinary factories, for most of them have tried and failed to make a living in open industry, many have been unemployed for years before entering the service of Remploy, and some have never worked before.

An analysis made in November, 1952, showed that 64% of the men were over 40, and 42% were over 50; more than a quarter were over 55. The women were relatively younger—only 26% of them being over 40, and only 10% over 50; but only about 350 women are employed.

On entry, most of the workers are quite unskilled in the trades Remploy has to offer them, and they have to be trained. Again, many of them have psychological difficulties associated with their disability, or with long unemployment. Moreover, idleness—as anyone who has been obliged to try it for any length of time well knows—corrupts the will to work. Again, when Remploy started, its workers were not entering long-established factories with a team spirit and a social life of their own; these things have had to be built up gradually. To begin from scratch, with employees who know nothing of each other, or of the work, is never an easy task; and the disabled, being as human as the rest of us, have among them old-soldier types who will do as little as they can for the money, and sea-lawyers who can air a minor grievance with a wealth of rhetoric. The number of such characters varies with the place in which the factory is set: some areas breed tougher types than others. Fortunately most of the workers in any of the factories are glad to find themselves in productive work again, and taking home a pay packet instead of collecting an allowance.

MATERIALS AND MARKETS

The problems in management which the workers present are at least equalled by the practical and industrial problems which Remploy has to solve. Thus it has to provide its factories where the disabled are chiefly grouped, not where the demands of industry could best be served. In some places it has been possible to take over Government premises, or to rent a factory; but quite often Remploy was obliged to build, and this has been expensive. The goods to be made have to be within the compass of the workers, not too tiring or heavy to handle, not exposing sick people to extra industrial risks (such as dust risks), and not likely to cause annoyance to any section of open industry by cutting across its lines of production. Remploy tries never to undercut the market price: its goods are sold at commercial rates, and sell on their merits. Materials have to be available in sufficient quantity; and steady markets are needed so that there shall be no "waiting time" in the factories. Morale is a delicate plant of slow growth, easily struck down, and the man who comes to the factory and does nothing for days on end may reasonably suppose that he is living on the nation's charity. He may also feel that when the next job comes along he had better spin it out. Both ideas hinder production.

With so many answers to find it is small wonder that Remploy has not always found the right ones. Its greatest difficulty has been in securing long runs and continuity of production.

Knitwear has proved a great success in these ways, and one at least of the group of six factories doing this kind of work has shown a profit. Cardboard-box making is also relatively successful, though here delays in getting some kinds of appropriate material have proved troublesome. Light engineering, and electrical assembly work, have in these days permanently good markets; and the "preservation, identification, and packing" (P.I.P.) of other manufacturers' goods for transport or export also provides steady work. There is a limited demand for such things as school and hotel furniture and bedroom suites; and surgical footwear and appliances are slow and expensive to make (whoever makes them). Other trades offered by Remploy include mattress-

making, printing and bookbinding repairs, strapmaking, textile sewing, the making of equipment for the Forces, and brush-making.

WORKERS ON PRODUCTION

One difficulty in the London area is to find suitable factories. The following brief account of three of them gives some ideas of the degree to which Remploi has overcome its difficulties.

I

The first, set in an industrial estate in a busy London suburb, is in an old factory, rented for this purpose, and not fully suited to its task: the windows are not large enough and the lighting system—by modern standards—is poor; but it is roomy and warm. It employs about 90 men in making orthopaedic footwear, callipers, tripod walking-sticks, crutches, 'Polythene' splints, and luggage straps. Their average age is 46. Their work was beautifully finished (this was true of all the work seen in Remploi factories), and in particular the orthopaedic footwear they were making was much lighter and more supple than that usually inflicted on the lame: many disabled patients know from experience where the orthopaedic boot pinches—or rather, how much it can weigh.

Great difficulty was experienced, at first, in getting the local hospitals to give this factory's work a trial. It was only when one hospital's supplier was snowed under with work that Remploi was given an order for a pair of shoes: the work was not only well done, but was done within a very few hours, and this hospital now always gives the factory a proportion of its orders for orthopaedic footwear. The men in the orthopaedic workshop were all cheerfully busy at the time of the visit, but some of those in the woodwork department were idle: orders had temporarily run out. It was evident that the men found this as unsatisfactory as the management—the difference in mood in the two workshops was noticeable.

II

The second factory, well to the east of London, in the dock area, takes about 110 men. No fewer than 18 of them are epileptics; and the medical officer of the factory—a general practitioner working part-time—remarked on the good effect of steady work on these patients. Many of them have lost job after job because of their fits. When they have had 3 or 4 fits on the factory premises without any attempt being made to get rid of them, they cheer up wonderfully, and as a rule their fit-rate falls considerably. This factory makes laminated furniture from wood veneers, turning out a great variety of pieces, from chairs and school furniture for the London County Council, to television tables. There are continuous markets for some of these goods (television tables seem to be a strong line at present). Others do not sell so freely, and some take long to make.

Much of the work requires a fair amount of active movement, or quite long periods of standing. Though none of the men questioned admitted to feeling tired, it seems likely that their output may have been slowed by fatigue. They have, however, a factory medical officer who is interested in methods of reducing fatigue, and ingenious in inventing devices for the purpose. They also have a good first-aid attendant, one of their own number who has been a bomb-disposal sergeant, whose concern for their well-being evidently gives them great confidence.

The men in this factory included some who were unstable, and at times inclined to violence. Remploi does not discharge workers because of troublesome behaviour except as a last resort, and after long months of trial and retrial; even then the discharge is made at the topmost level by the executive director. This ensures for the disabled the security they need; but it does not make any easier the task of management.

III

The third factory, in the suburb of a coastal city, employs only tuberculous disabled: Remploi has seven of these "special" factories scattered about the country. This one was built for its purpose, and while it is light, airy, and equipped with a good canteen (and a very good cook) it is short of storage space. It makes cardboard boxes, a commodity which cannot be compressed, and stacks of finished work stand about in every available corner, awaiting removal.

This factory, which will take 55, has 41 workers at present, 20 of them women. Most of the work is done sitting down, and it is neat skilled work, very suitable, it seems, for these people. Here again there is a good deal of machinery, but of course of a much lighter type, and more easily attended than that required in making furniture.

There was a cheerful pleasant atmosphere about the factory, where men and women were working together. They work hard and are keen on the job, but they tire towards the end of the day. Some attend the neighbouring hospital at intervals for pneumothorax refills or other treatment, and they are fatigued when they return. Most work full-time however; only 9 work half-time (four hours daily). The output here is better on the average than for many Remploi factories; and the manager hopes that as manual nimbleness improves, and as orders become continuous and steady, output will improve even more.

SOME FUTURE PROSPECTS

The managers of these three factories were of totally different types: what they had in common was an ability to get on with their workers, and a thorough knowledge of their own industries. They face at close quarters the problem which confronts Remploi as a whole: how to get each of their workers to contribute as much as he can without driving him to do more than he should. Remploi was established for the good of these disabled people, not to make a profit, so the managers probably err on the side of caution. One reasonable way of encouraging a man to do his best is to offer him a bonus on his output; and a bonus system has been introduced into one factory, making mattresses, with good success in stepping up production. But it would not do to introduce a bonus system in a factory which has much waiting time.

The first thing to ensure, then, is that Remploi makes goods for which there is a constant demand. This was pointed out by the Select Committee on Estimates¹ in 1952. The committee also made some useful suggestions on the organisation of sales on a trade basis instead of a geographical basis; but Remploi already had this in mind, and it has now been done, with advantage. Remploi also now has a managing director as well as an executive director and a financial director. These and various other changes have made it possible for Sir Robert Burrows,² the chairman, to note in his annual report a reduction of £62,613 on the previous year's loss.

Nevertheless, the loss for the year was high—nearly £2,380,400—and Remploi has plans for reducing it next year. Some of the factories are to be turned over to work which can command steadier markets, such as the assembling of electrical equipment, knitwear, and the making of elements for steam irons (which promise to be very popular). The cardboard-box factories can supply the containers for such small objects, and the P.I.P. factories can pack and dispatch them. With such steady lines it will probably be possible to introduce bonus systems into more factories, and so encourage production. Moreover, every year Remploi workers become more skilled in their trades, and newcomers are now entering factories with a good team and social spirit. Homework schemes, too, will be extended, and these should bring good returns because there are few overhead charges. A central sales showroom is to be opened at Cricklewood, and the export trade, which has just begun, will be developed. All these measures should help to bring down costs.

COSTS

Remploi workers get three-quarters of a normal full-time wage, even though their output is only a third of normal. This rate has been agreed with the trade unions. At present, as Sir Robert Burrows put it, the cost to each of us of employing these 6000-odd disabled people is 11½d. per head per year. It seems little enough looked at in this way; and there are some hidden advantages we get for our subscription which we all ought to take into account. Thus by March, 1953, Remploi had already returned some 1435 people to open industry: it had acted, in fact, as an unofficial reablement service. Again, though it would cost less, on paper, to pay these workers

1. Training, Rehabilitation, and Resettlement. London: H.M. Stationery Office, 1952.
2. Remploi Ltd., Annual Report 1952-1953.

from public-assistance funds, that would not allow for additional costs in sickness benefit likely to be needed by disabled people out of work, with nothing but their ill and failure to think about. The country, moreover, benefits by purchase-tax on Remploy goods sold, and by income-tax from the workers—figures which do not appear in the balance-sheet. Finally, some of the costs which do appear are merely figures on paper: thus, if a factory belongs to the Government, and Remploy pays rent for it, has money done more than circulate through a closed channel? Such rentals, however, help—on paper—to swell the figure for Remploy's trading loss.

Experts seem agreed there must be some financial loss on this project. Against this must be set its value, in mental and physical health and in self-respect, to the individual disabled person. We are willing to help these people at some cost to ourselves, and though we might do it a little more cheaply in other ways, the financial saving might not be worth the waste of spirit.

AMERICAN COLLEGE OF PHYSICIANS

FROM A CORRESPONDENT IN THE U.S.A.

As president of the Royal College of Physicians of London, Sir Russell Brain was the guest of honour at the 53rd annual meeting of the American College of Physicians, held in Chicago from April 5 to 9. He spoke on Cervical Spondylosis and on Problems of Cerebrovascular Disease, and he also lectured to the students and faculty of the University of Illinois College of Medicine. On less formal occasions he managed to astonish the few who still believe that "Britishers don't have a sense of humour."

The American College of Physicians was founded in 1915 by Dr. Kurt Stern and was patterned by him after the Royal College in London. Its fellows are selected from physicians in the United States, Alaska, Hawaii, Canada, Mexico, and the Caribbean Islands. The governing bodies consist of officers, regents, and governors. The officers and regents are an executive body and are chosen from former governors. Each governor represents the fellows of his State, province, or territory in North America, and, with governors from the United States Federal Services they number 67.

Election to fellowship in the American college usually comes after a three-year apprenticeship as an associate, and the fellowship is conferred each year by the president at the annual convocation.

Because the fellows are scattered over a continent and its islands, the headquarters in Philadelphia has never developed into a professional and social centre. To overcome the geographical problems, the American college holds small regional meetings and a large annual meeting in one of the important medical centres of North America. Here, each year, fellows, wives, and families congregate for a week of lectures, clinical and television demonstrations, panel discussions, and clinicopathological conferences. Besides these offerings and visits to local medical schools and hospitals, the main business of the college is transacted and a social programme is organised for the fellows and their guests.

The most important function of the college is the annual convocation. This year the processional of the officers, regents, governors, newly elected fellows, and distinguished guests was led by the president, Dr. LeRoy Sloan, professor of medicine at the University of Illinois. He conferred fellowships on 200 new fellows and masterships on four fellows. He presented the John Phillips memorial medal to Dr. Donald Van Slyke for his many contributions to clinical chemistry, and the James D. Bruce memorial medal to Dr. David Marine for his work on endemic goitre. He then conferred honorary fellowships on Prof. U.S. von Euler, of Stockholm, and on Sir

Russell Brain. In conferring the latter Dr. Sloan spoke movingly of the close ties between the American and London colleges, and he indicated that these bonds were to be further strengthened. At the end of the ceremony, Sir Russell Brain asked for the floor, and presented a gift from the Royal College of Physicians. This was a replica of the caduceus presented in 1540 by John Caius and carried ever since by the presidents of the Royal College. This was, Sir Russell believed, the first time that a president of the Royal College of Physicians had ever carried out official duties in the United States, and he was delighted to be at the convocation and to deliver in person the following message:

"We, the President and Fellows of the Royal College of Physicians of London, meeting in Comitia on January 28th, 1954, send by the hand of our President greetings to the American College of Physicians. Our two Colleges are united by a common tradition in medicine and by the constant interchange of new knowledge. We welcome this opportunity for strengthening the ties of friendship which already exist between many physicians in our two countries, and we offer to our sister College every good wish for her continued prosperity."

This message and the gift of the caduceus were greeted with obvious pleasure by the members of the American college; and when the processional withdrew from the convocation hall we noticed that Dr. LeRoy Sloan was carrying the caduceus in his hand. It is to be hoped that future presidents will carry on the tradition he has started.

PAY OF CIVIL SERVICE DOCTORS

THE pay of three grades of medical officer in the Civil Service has now been revised, and the new scales are to operate retrospectively from Jan. 1, 1952. They are:

Grade	Age	Salary Scales	
		Old scale	New scale
Basic grade	35	£ 1331 5 0	£ 1500
	36	£ 1382 10 0	£ 1575
	37	£ 1433 15 0	£ 1650
	38	£ 1485 0 0	£ 1725
	39	£ 1536 5 0	£ 1800
	40	£ 1600 0 0	£ 1900
		£ 1675 0 0	£ 2000
Senior medical officer	..	£ 1900 × 100	£ 2200
Principal medical officer	..	£ 2250	£ 2300

The negotiations which have led to this conclusion have been carried out by the Civil Service Medical Officers Joint Committee, composed as follows:

Dr. A. J. OWSTON (chairman); Dr. E. A. GREGG, Dr. A. MACRAE, Dr. D. P. STEVENSON, and Dr. H. K. COWAN (British Medical Association); Dr. N. R. BEATTIE, Dr. A. F. ALFORD, and Dr. E. MARTIN (Ministry of Health Medical Staff Association); and Dr. A. I. G. MCLAUGHLIN, Dr. J. H. MURDOCH, Dr. A. B. WALKER, Mr. STANLEY MAYNE (secretary), and Mr. T. H. PROFITT (Institution of Professional Civil Servants). As from the beginning of this year, the Ministry of Health Staff Association has brought its membership within that of the Institution of Professional Civil Servants.

The new scales are provisional in that both the committee and the Treasury remain free to put different proposals before the Royal Commission on the Civil Service. "This particularly applies to the rates of pay for senior and principal medical officers the increases in which both sides regard as purely token." Neither the recent increases in the salaries of hospital doctors nor any other change in the remuneration of medical work outside the Civil Service will be made the basis of a claim to the Treasury before the Royal Commission's report is published; but this in no way limits either party's freedom to use any such factors in its submissions to the Royal Commission, or to use any other new considerations in fresh representations either before or after the Royal Commission has reported.

The scale now agreed for the basic grade is not to be regarded as establishing any particular relativity between that grade and any non-medical grade in the Civil Service.

In England Now

A Running Commentary by Peripatetic Correspondents

ONE of the pleasures of Professor Aird's film on the *Conjoined Twins of Kano* lay in following the investigations which established, before operation, which structures did and which did not connect the infants. Simple palpation was most important, but radiological, electrocardiographic, and radioactive isotopic methods also provided essential information. As a physician, I may say that I think that surgeons often have a lot to teach us in the use of direct, intelligent step-by-step elucidation of clinical problems. But surgeons have no monopoly. The morning after I saw the film I went to the garage in my car, which was making a new noise, like water running into a deep cistern. Not very loud, but I feared what it might portend, and like a mother with her child I wanted reassurance. Nevertheless I behaved correctly and consulted the vehicle's usual attendant, although I knew his liking for gloomy prognosis. He listened. "Specialist job," he said.

The specialist was of middle age and below medium height, clothed in an immaculate white gown like those worn by some doctors in hospitals in France. He asked me what was the matter. "It's the noise," I said, "transmission, I think." He listened there and here. "Probably magneto or water pump. Can you spare five minutes?" "Well, yes, but I can't spare half an hour. I have to go to hospital." "When we say five minutes we mean only six," he replied with a smile—a model for every consultant who wishes to temper authority with humour.

Two assistants in brown overalls arrived, towels were draped over the mudguard and in no time the fan-belt was off. I started the engine, the noise had gone. "Yes, magneto or water-pump. Joe, would you mind fetching the stethoscope? The telescopic one as well as the other. Thank you so much. And Bill, would you put the fan-belt on again?" The monaural telescopic and the binaural ordinary one arrived. The ear-pieces of the latter looked just like mine, except that the nickel plate was not flaking off and the rubber tubing was clean. The chest-piece, if I may so call it, bore a narrow metal rod about six inches long. The specialist applied its tip here and there systematically, with the engine running. "Yes," he said, removing the stethoscope, "water-pump. Now we'll order the replacement and you bring her in on Monday."

I should not push the surgical analogy too far, but I must admit that I paid no fee for the consultation and expect a whopping bill for the operation.

* * *

It is all very well for you, Sir, to affirm editorially that "enteric infections due to bathing beyond reasonable doubt are few," but you have not attempted to answer the really ticklish question of when a bather can be said to have bathed beyond reasonable doubt. Any wretched member of the party who gets up early may appear before breakfast looking virtuous and wringing out a wet bathing suit for all to see, but such evidence is obviously suspect. Unfortunately no-one has really ever defined the borderline between paddling and bathing. I would put the line at the pubis. The shock I get when the first wave splashes my perineum is something quite distinct from paddling, but if one retreats at this stage I'm afraid there is still reasonable doubt about the bathe. Some would accept a wet abdomen; others demand a wet neck or even wet hair; but no doubt, allowing for enteric, the editorial criterion would demand total immersion with a good swallow of sea water.

* * *

I often breathe a sigh of relief that Jim Dale and his partner seem to cope so effectively with the ailments of Parkwood Hill; Mrs. Mountford would be off my list after the first quarter. I should hate to be called in to attend the Huggetts, and if the Archers lived a bit nearer they would find me very short-tempered with Philip at times. But no practice can thrive on such a negative philosophy, so there are now seven new names on my list since the cards for the Grove Family arrived this month.

You know how it is when you take on a new family; you tend to make a snap judgment of their relative nuisance values to the practice. The Grove household shows all the signs of being another matriarchy, with weekly anarchical fugues, so the prognosis seems likely to follow the basic patterns of petticoat rule. Grandma's autocratic hold is getting shaky and it obviously won't be long before I am digging the Authorised Officer out of bed to cope with the old girl's senile dementia. Mrs. Grove is shaping up pretty fast to take on Grandma's crown while it is still warm.

Both Mr. and Mrs. Grove carry enough middle-aged spread to make constant demands for 'Dexedrine' a dead cert within the next six months, and I suspect that Mrs. G. is going to be rather tiresome to steer through her looming menopause on account of the psychosomatic factors in the household.

Mr. Grove suffers from the initial disability of not being master in his own house, and if I can manage to sustain him from anxiety neurosis I rather fear that he will throw a duodenal ulcer on us.

On the whole I feel confident that I can grapple with the more mature members of the Grove Family, but the kids would make any G.P. wonder if they are worth their capita-tions. That scrounger Jack reminds me of my Service days; M and D for you, my lad! And let's hope that the Army knocks a bit of sense into you where your father has obviously failed. Pat is going to be hard to convince that a lot more early nights and a lot more protein in her lunches would be better than burning the candle at both ends. I won't be able to do much for her shallow mind, but I really would like to keep tubercle out of her apices until the penny drops and she settles down. Daphne is my main hope despite her tender years. I think I shall have to take her into consultation to get the low-down on the rest of the family. And then there is Lennie—the sooner we ship him and his behaviour problems off to the nearest child-guidance clinic the better, otherwise the poor tax-payer will have to find another £8 10s. a week to keep him in an approved school.

Well, there they are, seven little cards beaming at the kindly executive council, seven more wrinkles to furrow a practitioner's weary brow, seven more peripheral grey hairs. Look in and see for yourself the wealth of clinical material while I try and find an easier way of earning a living.

* * *

The other evening, on my return home from work, late and exhausted, my wife said: "You know, doctors are paid too much." I digested this awhile, and after due thought replied: "I think you mean that teachers are not paid as much as they should be?" "Exactly."

Ruminating upon my correct interpretation of her remark I came to the conclusion that she probably needed a new evening dress. To confirm the diagnosis, I remarked: "By the way, you know it's three years since I had a new suit? Do you think I can go on much longer in this one?" "Well, you are whole-time, and you're an S.H.M.O. . . ." I accepted both rebukes, and at that moment the B.B.C. announced the magnificent award to hospital staff. "There you are," says she, "you'll get at least £50 more: surely you aren't so mean as all that?"

During the past week she has ordered: (1) a new car at £550; (2) an evening dress at £31 10s.; (3) an alteration to her fur coat at "approx. £28"; (4) a new shirt for me at £3 3s.

* * *

My assistant and I bent over the foul-smelling post-mortem. The surgical registrar who was looking on fished his pipe out of his pocket and lit it. But presently it was too much even for him and he walked out. As the door closed behind his back, my assistant heaved a great sigh of relief. "Thank goodness," he said, "that fellow has taken his pipe away."

* * *

Clinician: Why are you looking at those skin biopsies?
Pathologist: I'm trying to sex them by this new-fangled idea of studying the nuclear chromatin.
Clinician: Then you will issue a Skinsey report I suppose?

Letters to the Editor

TUBERCULOSIS IN ADOLESCENCE

SIR,—The recent Ministry of Health circular,¹ to which you refer in your leader of April 17, calls for action.

Some may think that we have hardly reached the point when tuberculosis can be dealt with on epidemiological lines like smallpox or typhoid fever; but all will agree that new and greater effort is called for in many branches of our anti-tuberculosis organisation. A vigorous drive is certainly needed to diagnose the disease more often in its earliest stages.

I have been impressed, in recent years, by the finding of adult-type disease in school-children who happen to have been examined by mass radiography. The disease in adolescence has a strong tendency towards inevitable deterioration if energetic measures are not taken. If the disease in young people is not dealt with at an early stage, treatment will, in most cases, be demanded in later years when the chances of success may be much reduced.

Among 14-year-olds mass radiography reveals 1.1 new cases of active tuberculosis per 1000 boys and 1.7 per 1000 girls,² but the method has so far only been applied in a patchy way. Has not the time arrived to extend the use of mass radiography in young people towards the end of their school careers? Such a proposal is hardly new, for a scheme of this sort was advanced in 1936 by Wingfield and Macpherson.³

Another recent Ministry circular,⁴ which gives local authorities powers to inoculate 13-year-olds with B.C.G. vaccine, points the way. Local authorities who implement the new scheme will find that approximately 40% of children have already been infected with tuberculosis. It is very much to be hoped that these children will be promptly radiographed, for it is certain that they will provide a useful harvest of early cases of pulmonary tuberculosis, many of adult type. Obviously, all the cases which may be revealed by mass radiography will be in this 40% who are already tuberculin reactors. It is likely that, taking one year of age only (say, 13 or 14), a single careful examination would bring to light 18 new cases of active tuberculosis in every million of the population (approximately 13,000 children at, say, 1.4 per thousand); and it would only be necessary to radiograph approximately 5000—the 40% known reactors. It is to be hoped that local authorities and regional hospital boards will consider what this would mean in their own areas and decide that it is both practicable and worth while.

Pulmonary tuberculosis of adult type in young people has, in the past, generally been so scattered that few can claim much experience with this age-group. My colleagues and I have recently reported⁵ on 116 such cases treated in a sanatorium for long periods and subsequently followed up for an average of over six years. Collapse therapy was used extensively, but antibiotics were not yet available. Selected cases did well with an artificial pneumothorax, but the over-all results left much to be desired. Long-term investigation of a more recent series would probably show greater improvement with modern chemotherapy. So far, however, there can be no final decision on the most effective therapy. Many adolescents will certainly require sanatorium treatment, perhaps combined with antibiotics and collapse or resection. Treatment should be undertaken only in

centres where adequate education can be given. Possibly some youngsters may be allowed to continue, under expert supervision, at ordinary schools. Special registers of these cases should, in any event, be compiled in appropriate areas so that they can be followed up in groups large enough for helpful analysis. In this way knowledge would be gained not only of the disease in school-children, but of its often insidious development in young adults.

High Wood Hospital for Children,
Brentwood, Essex.

F. J. BENTLEY.

SPREAD OF INFLUENZA IN THE HOUSEHOLD

SIR,—The paper from Cirencester by Dr. Hope Simpson and Dr. Sutherland in your issue of April 3 is a most interesting example of the information which can be gathered by careful observations on that fundamental epidemiological unit—the family or household. The success of timing of the occurrence of cases of an infectious illness as a means of proof of the mode of contagion must, however, depend upon the accuracy of the recognition of each infection. The latter, in turn, calls for a recognisable clinical phenomenon as an accompaniment of infection, or else must be based upon laboratory findings.

Diseases such as measles, which exhibit characteristic rashes, thus afford good material for analysis, and it is hardly surprising that the actual occurrence of cases in the family agrees so well with the predicted numbers based upon a person-to-person chain of infection.

Similar observation on cases of influenza is handicapped in two ways: firstly, by the occurrence of other febrile respiratory diseases resembling influenza but not due to the influenza viruses; and, secondly, by the known frequency of subclinical infection as a result of exposure to influenza viruses. The first difficulty would be likely to obscure the findings by inflation of the figures for the number of cases in the household, whereas the second one might prevent the expected wave of secondary cases because of the exhaustion of susceptibles by this mode of infection. Whether or not these arguments are valid as an explanation of the irregularity of the influenza data presented by Dr. Hope Simpson and Dr. Sutherland, it would seem necessary to urge the need for laboratory confirmation of the occurrence of infection in future studies of this kind. Nevertheless, the variable pattern of behaviour of influenza, as judged on a purely clinical basis such as the authors describe, is in keeping with the variable epidemiological pattern seen in the community as a whole, and also, may it be added, with the remarkable variability of the characters of the causative viruses and of the still-undefined human properties of susceptibility or resistance to their attack.

TREATMENT OF VARICOSE ULCERS

SIR,—I would like to support Mr. Murley (April 10) in his criticisms of some of Mr. Lee's suggestions (April 3) for the treatment of "varicose" ulceration. Arterial spasm plays a very small part in the causation of the vast majority of varicose ulcers, a fact which was well demonstrated by Brewer¹ of Liverpool. In his series he proved by arteriovenograms that the ulcer which was due to arterial spasm was rare. It is in this small group that sympathectomy, or the alternative of injection of the femoral artery with tolazoline, might possibly give some benefit. It is to be hoped, however, that Mr. Lee will confine sympathectomy and injection of the femoral artery to this rare group and that the remainder will receive the accepted treatment, whose benefits we all understand so well.

1. Prevention of Tuberculosis. Circular H.M.(54)30.

2. Report of the Ministry of Health, 1952.

3. Wingfield, R. C., Macpherson, A. M. C. *Brompton Hosp. Rep.* 1936, 5.

4. Circular 324/B.C.G., 1953.

5. Bentley, F. J., Grzybowski, S., Benjamin, B. *Tuberculosis in Childhood and Adolescence*. London, 1954.

Compression treatment is the sheet anchor in the treatment of varicose ulceration. This fact has been shown to us throughout the ages, especially by Thomas Baynton in the eighteenth and Benjamin Brodie in the nineteenth centuries. Recently we have to thank Bisgaard for calling our attention to the immense value of physiotherapy, and Cockett and Elgan Jones² for simplifying what they term so aptly "the ankle blow-out syndrome." The skill in healing thrombotic ulcers lies in the correct timing of *when* to use these three cardinal factors in treatment. As a rule, compression will give us a slim and healed limb; massage will then still further improve the leg; and finally the removal of the "short-circuited circulation" above and around the ankle will complete the treatment, even though in certain cases a changed "way of life" may be required.

London, W.1.

R. ROWDEN FOOTE.

REMUNERATION OF HOSPITAL MEDICAL STAFF

SIR,—I have been wondering why I am pleased with the recent award of pay increases to hospital medical staff, while so many of my colleagues feel that it is not enough. I have now realised that when I became a tuberculosis officer in 1941 my income was £600–800 per annum, and now, though graded S.H.M.O., it will be £1500–1950—a betterment factor of 150%. There must be others with a similar experience.

Clearly, some redistribution of income within the profession has been taking place, and viewed dispassionately this would not seem to be a bad thing. The justification for very large incomes for consultants in the past was surely in the lean years, during which their incomes varied from nothing as a houseman to the odd hundred or two as a registrar later on. The path has been made easier, though perhaps, as a result, the competition is now fiercer. Surely the demand for 100% increase for everybody is unrealistic and would only perpetuate the injustice to the lower-paid ranks. The negotiators have done well, in my opinion, to distribute the available sum where it will be most appreciated.

When we compare ourselves with the general practitioners, there is room for disappointment, especially as the hospital medical staff award is not retrospective to 1948. But again, as you say in your leader of April 10, future experience will show whether the correct balance will be found, and sufficient recruits attracted to all sides of the profession. The Cinderella of the health service now is Public Health, and every effort should be made to help our colleagues there in this just claim.

Liverpool, 18.

WILLIAM D. GRAY.

SIR,—The majority of S.H.M.O.s occupy posts carrying full clinical responsibility, and in fact work as consultants. We must have considerable value as "cheap labour" in the National Health Service. Unfortunately, we have little or no bargaining-power, and our posts could easily be filled by registrars in search of financial security. Could this be why we have received an increase in our rate of pay of 15.4% as against 23.5% for the consultants?

Queen Alexandra Hospital,
Cosham, Portsmouth.

A. M. READ.

SIR,—Surely we are all agreed that the award which junior hospital doctors have just received is ridiculously inadequate. It is neither retrospective nor untaxed, and bears no relation to the increase in the cost of living since 1948.

If this award goes unchallenged we shall probably receive another £75 or £100 in 1960! It is understandable that each section of the profession has its own economic interest at heart, but if these token awards are to be stopped, the B.M.A., in its proper rôle of a trade union,

must press the claims of each section of the profession as a whole, and refuse piecemeal settlements, such as the Danckwerts award, which leave the claims of other sections of the profession unsettled.

Only when this happens will we be able to reject these awards, knowing we are in a strong enough position to do so.

Norwich.

J. M. BROWNLIE.

SIR,—Now that salary increases for hospital medical staff and consultants have been finally agreed on, is it not high time National Service medical officers' pay was increased? Recent Service increases expressly omitted National Servicemen.

One reason that National Servicemen are not paid so much as their Regular contemporaries is to try to persuade some to apply for permanent commissions; but we, especially those who are married and trying to build up some sort of home, have to exist in comparative penury. There are no allowances in lieu of married quarters (no accommodation is provided for National Service medical officers) and the marriage allowance is less (two-thirds) than for Regulars.

At one time the rates of pay of house-officers and National Servicemen may have been adjudged to approximate (with the perquisites available to some house-officers the difference was greater), but now this can no longer be true, especially for any who held senior house-officer posts prior to call-up.

NATIONAL SERVICEMAN.

REPAIR OF LARGE HERNIÆ

SIR,—Your issue of Feb. 20, containing Professor Stock's account of the use of nylon mesh in the treatment of inguinal herniæ, has just arrived.

"The use of implants of foreign material," he says, "is almost as old as the history of operations for hernia . . . but most attempts have failed because of undesirable tissue reactions and sepsis." Surely there is only one type of tissue reaction to the introduction of any sterile foreign material into the human body—an aseptic inflammatory response that may or may not proceed to pus formation irrespective of actual infection introduced at the time of operation. Indeed, the essence of all operations of this type is the induction of just this type of response, with the production of a strong fibrous wall which, it is hoped, will take the place of the weakened muscles in the posterior inguinal wall.

Perhaps the greatest weakness of all "implant" operations, applied to indirect inguinal herniæ, is that they concentrate attention on the repair of the posterior inguinal wall, instead of on the re-creation of a functioning internal ring. But, as Ogilvie pointed out many years ago, in indirect herniæ the primary site of weakness is not the posterior wall but rather the stretched, weakened internal ring. Professor Stock does not say how many of his "ten patients with inguinal hernia" actually had indirect herniæ, but he implies that his operation may be used equally well for either direct or indirect. Surely there is a distinction to be made between the two.

He adds that "if the testis is abnormal or there is a thick hydrocele sac, orchidectomy is usually performed," which is a curious statement in this context. If an indirect hernia has reached such a stage that the internal ring and the posterior inguinal wall cannot be functionally re-formed, then the prospect has to be considered of complete closure of the canal, usually (though, as Aird points out, not necessarily) with orchidectomy. This, like all other forms of herniorrhaphy, does not guarantee against recurrence; and the patient, as well as the surgeon, must weigh the relative advantages which orchidectomy and complete closure of the canal offer. But in the treatment of hernia, it is the hernia that determines the necessity or otherwise of orchid-

2. Cockett, F. B., Elgan Jones, D. E. *Ibid.*, 1953, 1, 17.

ectomy, and not the state of the testis, let alone the state of the sac or tunica. To say that orchidectomy is usually done "if the testis is obviously abnormal" is surely irrelevant in this context: to say that it is usually done if "there is a thick hydrocele sac" is a little radical. When else would one do an orchidectomy for hydrocele?

Inexpensive, ubiquitous, malleable, and indestructible, nylon may be; and it is perhaps some comfort to know that when we have shuffled off our mortal soles the immortal uppers will still live on: but will they help my hernia?

Ilesha, Nigeria.

H. J. WRIGHT.

IDENTIFICATION OF DRUGS

SIR,—We are interested in the letter from Dr. King, in your issue of April 10.

This company manufactures its tablets with an identification mark, and we issue, on request, details showing which marks coincide with which drugs. Furthermore, in our advertisements in the medical press, we often show a picture of the actual tablet so that doctors may become familiar with the marking on the tablet. We know that some other manufacturers adopt somewhat similar policies.

Bayer Products Ltd.,
London, W.C.2.

L. M. SPALTON
Director.

TREATMENT OF DEAFNESS

SIR,—In your issue of March 13, Mr. Robin warns the medical profession and its hard-of-hearing patients against "claims made for improved hearing by re-education methods."

It seems that he has, once again, confused the purely physical ability to hear with hearing in its broadest sense—namely, the ability of the cerebral cortex to interpret and respond to the auditory signals it receives from the ear in the course of daily hearing.

It is hard to say why Mr. Robin wishes to give your readers the impression that auditory training is said to improve the patient's physical ability to hear, when no such claim has been made. The very term implies that auditory re-education deals solely with cortical hearing. Obviously there is no simple, single, "scientific" test or measurement for a complex function which embraces a wide variety of auditory achievements such as recognition, discrimination, reaction-time, and memory for an endless variety of sounds received under dozens of different conditions, and which, in the hard-of-hearing, is further governed by fear, doubt, fatigue, lack of confidence, and even personality change.

Yet Mr. Robin demands that these aspects of hearing, and any change therein, be gauged by tests designed solely for gauging physical change in the peripheral auditory mechanism. Without such "scientific proof," he says, there can be no improvement in hearing, even though the patient's relations, associates, or employers state freely that it is very evident that the patient hears better. When confronted with such evidence, Mr. Robin mistakes cause for effect and seeks refuge in the suggestion that the patient's ability to "listen" has improved, even though we have painstakingly shown him that the improvement included sounds and conversations for which the patient could not possibly be listening.

As an aural surgeon, Mr. Robin must recall that the rather unscientific "social adequacy index" was adopted to assess hearing improvement in fenestrated cases, simply because pure tone and speech audiometry too often failed to portray the clinical results.

At this unit we assess improvement by what, in our opinion and long experience, is the most comprehensive way of depicting the results of auditory rehabilitation—the hearing disability questionnaire. This lists and indicates graphically the patient's stated ability before and after re-education for: conversation across a desk and a room, round a table, and in groups; speech and sounds other than speech (bells, buzzers, sounds from behind him, and from room to room); telephone, television, radio, confidential tones, whispered speech, and so on. Mr. Robin makes no mention of this in his letter. It might interest him to know, and to inquire why, the results of rehabilitation of the orthopaedically handicapped

are also assessed and recorded in such homely and "unscientific" terms as "turning over in bed," "combing and brushing the hair," "drinking from a glass," "walking up and down stairs," "striking a match," and so on.

The tone of his letter implies that auditory re-education is a worthless quackery whose "principle needs medical and scientific investigation before the practice is recognised as of true value," when in fact its use, both with and without hearing-aids, has long been practised in many of the most important auditory rehabilitation centres of the world.

Mr. Robin's motives are not to be questioned, but it is to be regretted that he has seen fit to voice his opinion publicly and dogmatically on the worth of a very specialised field of endeavour—after only a half-hour's exposure to it. In seeking to protect the hard-of-hearing public from being exploited, he has only succeeded in directing them away from the type of help they so sorely need. We trust that this letter will be able to undo the harm.

London, W.1.

ELIZABETH CHADWICK.

CHEMICAL STRUCTURE OF SULPHONAMIDES AND THEIR EFFECT ON PERISTALSIS

SIR,—The effect of phthalylsulphacetamide on intestinal peristalsis was mentioned in your journal last year¹; so I am writing to draw your attention to some experiments done in Germany. These have shown that the action of various sulphonamides on peristalsis is closely related to their structure.

Enders^{2,3} and Kleibel^{4,5} have found that certain groups of sulphonamides inhibit peristalsis, apart altogether from their antibacterial action in intestinal infections.

Sulphathiazole ('Cibazole,' 'Eleudron'), sulphapyridine ('Eubasine'), and phthalylsulphathiazole⁶ ('Taledron') inhibit peristalsis in experimental concentrations of about 1:2000, which should be attained with a dosage of 8–10 g. daily in the human subject. Their chemical structure shows a benzolsulphonamide group attached to a ring containing a single N-atom (fig. a). If benzolsulphonamide is combined in a molecule with a ring carrying a double N-atom (b), as in sulphapyrimidine ('Debenal') or sulphadiazine, or if this ring is replaced by

an aliphatic chain (c), as in sulphacetamide ('Albucid'), sulphaguanidine, and phthalylsulphacetamide, peristalsis is inhibited only at an experimental concentration of about 1:500, which would require a dosage of 36–40 g. daily in man. In other words, the quantity needed to inhibit peristalsis has to be four times as great.

1. *Lancet*, 1953, 1, 831.
2. Enders, A. *Dtsch. med. Wschr.* 1951, 76, 1404.
3. Enders, A. *Dtsch. Z. Verdau. Stoffwechsellkr.* 1953, 13, 236; *Arch. exp. Path.* 1943, 201, 366.
4. Kleibel, F. *Dtsch. Z. Verdau. Stoffwechsellkr.* 1952, 12, 257.
5. Kleibel, F. *Ibid.*, p. 183.
6. Henning, N. In von Bergmann, Frey, and Schwiégk's *Handbuch der Inneren Medizin*. Berlin, 1952; vol. III, part 2, p. 37.

Finally there is another sulphonamide, aminomethylbenzolsulphonamide ('Marfanil'), which has been shown both experimentally and clinically to excite peristalsis instead of inhibiting it. This preparation differs from those previously mentioned in having an NH_2 group joined to its benzole ring by a methyl group (*d*). It is interesting to note that it also differs from the others in its effect on intestinal bacteria.

These actions were demonstrated on the gut of rat and guinea-pig, and they did not persist longer than one hour. Desensitisation may thus be ruled out.

Medical Polyclinic,
Würzburg University.

FRANZ KLEIBEL.

THE RECENT BURN

SIR,—Correspondents have lately discussed the desirability of leaving blisters intact when dealing with minor burns in industry. I have found that undiluted 1% electrolytic sodium hypochlorite solution, applied immediately in the form of a compress, prevents the formation of blisters; or if they have already formed on a recent burn, they are quickly reduced. Since the skin remains unbroken, there is absolutely no risk of infection with this method; moreover, it takes very little time, and pain is much reduced. If the skin is broken, the hypochlorite should be diluted to form an isotonic solution.

London, W.1.

M. MARGARET DURRANT.

TREATMENT OF THYROTOXICOSIS WITH POTASSIUM PERCHLORATE

SIR,—We should be grateful if you would allow us to add a postscript to our article of April 10. We there described a patient whose gastric symptoms became much worse when her treatment was changed from methyl thiouracil (50 mg. daily) to potassium perchlorate (100 mg. daily). The dyspepsia disappeared when she was put back on methyl thiouracil, but reappeared a second time when potassium perchlorate was given. She was known to have a diaphragmatic hernia, and we concluded that perchlorate was probably irritating an already inflamed gastric mucosa.

Further experience with this patient makes this conclusion unlikely.

After another period on methyl thiouracil the gastric symptoms again increased, and became incapacitating. They mainly occurred when she went to bed at night, and consisted of severe epigastric pain and vomiting. These symptoms were only partially controlled by outpatient therapy and she was admitted to hospital. After a few days' treatment by posture, diet, and alkalis the symptoms rapidly subsided, and we took the opportunity of testing the effect of potassium perchlorate under controlled conditions.

For four consecutive 5-day periods she was given tablets of identical appearance, labelled A, B, C, and D, to be taken twice daily. Tablets A and C contained lactose only, tablets B and D contained 200 mg. of potassium perchlorate. The content of the tablets was not known to the patient, the nursing staff, or the clinical clerk who recorded the symptoms daily. During the 20-day test period only one attack of epigastric pain and vomiting occurred. This happened while she was taking tablet A (lactose). At the time of the test potassium perchlorate clearly did not irritate her gastric mucosa, although gastric symptoms had recently been present and the mucosa might be expected to be in a sensitive state. It seems probable that the exacerbations of dyspepsia twice observed in the past when she was taking potassium perchlorate were not caused by the drug.

This was the only case, out of 108, in which there seemed to be good evidence of gastric irritation by potassium perchlorate. Since further experience has shown that this evidence was probably misleading, it now seems unlikely that potassium perchlorate will prove to be a gastric irritant, although this possibility must still be kept in mind.

University College Hospital
Medical School, London.

M. E. MORGANS
W. R. TROTTER.

METHYLPENTYNOL AS A HYPNOTIC FOR OLD PEOPLE

SIR,—Most elderly patients require some artificial aid to sleep, but the range of suitable hypnotics for routine use is very limited. The drugs commonly used include paraldehyde, chloral hydrate, sodium bromide, the traditional "Mist. Three-fifteens," and—most widely used of all—the barbiturates (mainly the "medium-acting" and "short-acting" ones). For old patients nearly all these hypnotics have some disadvantages.

I would like to report a trial of a comparatively new hypnotic drug, methylpentynol ('Oblivon'). Although its chemical structure bears superficial resemblances to paraldehyde and to methyl alcohol, methylpentynol is a separate drug in its own right. Methylpentynol (methylparafynol in U.S.A.) is a simple unsaturated aliphatic carbinol, 3-methyl-pentyne-ol-3, having the structural formula: $\text{CH}:\text{C}(\text{CH}_3)(\text{OH})\text{CH}_2\text{CH}_3$.

The literature on this drug has been reviewed¹ but, with the exception of a limited study of the drug in fifty-two psychiatric patients aged 61 and over,² the usefulness of methylpentynol as a mild hypnotic for the elderly has received little attention.

All the patients studied were aged 65 years or over. The report is based on a series of ninety-four patients, of whom thirty-two were aged 65-74, forty-three aged 75-84, and nineteen aged 85 or more. There were twenty-eight men and sixty-six women. All were general hospital patients and were under continuous observation, day and night. The great majority had required regular dosage with other commonly used hypnotics, with variable effect and for varying periods, up to the time of beginning methylpentynol treatment. Only those who received the drug continuously for a minimum period of 7 days or more were included in this study: thirty-eight patients received the drug nightly for 21 days or more, and twelve for 42 days or more. The minimum total dosage was 6.7 g., the maximum 144 g. The longest trial was in a man aged 76 who received a total of 144 g. over a continuous period of 72 days.

Method of Administration.—The unit dose of methylpentynol is 250 mg., and this was incorporated in one drachm of elixir specially prepared by the manufacturers. Any drug, if sufficiently soluble in water and not objectionable in taste, is more conveniently given to old people in liquid form rather than as tablets or capsules. The crude drug, methylpentynol, is a volatile liquid with a vile burning taste, far worse than paraldehyde, and it was therefore originally dispensed in capsules. For the purpose of this study, however, it was incorporated in an elixir, which disguised its taste. The most effective dose was 4-6 drachms (1.0-1.5 g.). Smaller doses seldom had a hypnotic effect, and larger doses had no added advantage. Altogether, forty-four patients received a dose of 4 drachms nightly for periods varying from 7 to 59 days; forty-eight were given a nightly dose of 6 drachms for periods of 7 to 49 days, and twelve were given a dose of 8 drachms nightly for periods ranging from 12 to 72 days.

Assessment of Efficiency.—The effectiveness of the drug on each individual was observed by doctors and by senior nurses, who also recorded every half-hour during the night whether or not the patient was asleep. Special charts were used and records were kept every night while the drug was being given. After the trial, the hypnotic effect for any night was noted as "good" if after the dose had been given the patient had been asleep within 1 hour, and had remained asleep for at least 5 hours. The response was noted as "poor" if sleep was broken, or had not ensued within 2 hours of giving the drug, regardless of the duration of sleep. In any particular patient, the drug was said to have been "efficient" if a "good" night's sleep was obtained on 70% or more of the nights on which it was given.

Results.—In sixty-one of the ninety-four patients (64%), the drug was found to be "efficient." Its prolonged use gave no troublesome side-effects, and there has been no evidence of addiction. When the hypnotic effects wear off, patients remain quietly sedated and do not become restless or noisy, so there is usually no need to repeat the dose during the

1. *Brit. med. J.* 1953, ii, 435.

2. May, P. R. A., Ebaugh, F. G. *J. Amer. med. Ass.* 1953, 152, 801.

night, and excessive drowsiness next day is thereby avoided. The hypnotic action is a mild one, and the drug will not produce sleep in the presence of pain or acute mental disorder.

Thus, methylpentynol was found to be an efficient hypnotic in almost two-thirds of these patients. It appears to be a useful drug for elderly patients needing a mild hypnotic; and it is apparently safe and free from troublesome side-effects.

I should like to thank Dr. A. G. Anderson, Dr. A. W. Hendry, and Dr. W. R. Gauld for permission to include patients under their care in this investigation. I am also indebted to members of the nursing staff at Glenburn Wing, Woodend General Hospital, Aberdeen, for their willing co-operation. Methylpentynol elixir was supplied by British Schering Ltd.

RONALD G. SIMPSON.

MOUTH-PIECE FOR USE WITH PNEUMOFLATOR IN RESPIRATORY PARALYSIS

SIR,—In your issue of Dec. 12 Dr. Beaver and Dr. Gilliatt described a cheap and simple improvisation of a mouth-piece for use with lung inflators. It was devised to take the place of the face-mask which is commonly used with these machines in maintaining artificial respiration. In this hospital we have had long experience in methods of artificial respiration, particularly for poliomyelitis, and we were fully aware of the difficulties encountered when using the face-mask in the conscious patient. Since the description of this mouth-piece was published, we have had the opportunity to give the mouth-piece (and modifications of it) an extensive trial in two intelligent adult patients. Both were loud in their praises for a device which they could accept with great comfort where previously, with face-masks, they were anxious, even alarmed, and almost certainly under-ventilated at times, even when the mask was being applied correctly.

W. HOWLETT KELLEHER.

NURSING BY THE MOTHER

SIR,—This correspondence has arisen out of the subject of cross-infection in hospitals, raised by the Pickerills in their article of Feb. 27; but I would like to add these comments in support of Dr. Lowenfeld's letter of April 10. She emphasises (1) the structure and organisation of the hospitals in which children are treated; (2) reconsideration of the training of nurses who will care for them and study of the ways in which help of the mother can be enlisted; (3) the value of play in recovery from illness. Homesickness and, above all, boredom work against recovery, and play is the only palliative.

There are many who agree that small children admitted to hospital should be accompanied by, and nursed as far as possible by, their mothers, but rather few, I fancy, who have found it easy to put into practice. This is where structure comes in. In most modern children's units and adapted old wards, the cubicles are too small to accommodate both mothers and children; the bathing and lavatory arrangements for the mothers are makeshift, and there is no sitting-room, dining-room, or telephone for them.

If it became known to the public that arrangements were adequate and that mothers were expected to go to hospital with their babies and keep in touch with home from this outpost, the neighbours would feel their obligation to step into the breach more binding than they do at present—in the south of England, at any rate.

Our nursing-staff difficulties are going to increase, not diminish, and although children usually get a better deal than adults when shortage is acute, the staffing of wards at night often reaches dangerously low limits.

On the second point—"Reconsideration of the Training of Nurses" (and doctors, I would add)—it is often felt, if

not actually declared, by those who have charge of sick children in hospital that the parents of a child are not good for it. The child may be brought in in a dirty condition; the hair may have nits; a distressing emotional scene occurs at each visiting-time; or the feed the baby was having may be "a bit out" by ordinary calculations; and, as if any further proof were required that the parents are to blame the child under proper nursing gets well, gains weight, looks rested, and, above all, looks clean. Is it surprising that nurses and doctors see little to change in the time-honoured method of taking over completely from the mother? When we admit a child to hospital, mentally we nail a notice over its cot or on the door of its cubicle—Under New Management.

At present, nurses in training hardly notice the parents in the picture. They certainly cannot have an opportunity of seeing mother and child as one, and they are rather too young to have a serious interest in the mother's character and competence. Ward sisters, on the other hand, have to develop what may be called critical sympathy with the mothers, and some have a special gift for it.

The new orientation will make big demands on them in that it requires much further study and the sacrifice, to some extent, of the bond they would normally have with the child. Having seen it begin to work in a paediatric unit (in spite of the structure being unsuitable), I am moved to write this letter.

Department of Paediatrics,
Stoke Mandeville Hospital,
Aylesbury.

DERMOD MACCARTHY.

THE HOSPITAL MAKES FRIENDS

SIR,—The letter by "Registrar in Teaching Hospital" (April 10) illustrates the difficulty of conveying in writing a precise point of view. Writing as a psychiatrist, I assumed that, by the wording of my letter of March 10, it would be clear to your readers that I was not a general practitioner. I wonder whether it is not a common fault for people to interpret what they read in terms of their own problems.

At one clinic at which I worked before the late war, we had a weekly case-conference to which all concerned were invited. I feel this made for co-operation between the clinic and the general practitioner, as well as between other social services connected with the welfare of the patient.

Bishop's Stortford,
Hertfordshire.

D. N. HARDCASTLE.

A WORD WANTED

SIR,—With Dr. Apley's search for the best antonym to "retrospective" (April 10), I have that sympathy which comes from failure, partial or complete, in a similar quest. In my own attempt,¹ I finally settled for "prospective," not too happily, since this word has acquired connotations other than that desired. In my private vocabulary at the time, I used "Promethean" and "Epimethean" to make this contrast; and I just wonder if a transfer from upper to lower case might not supply Dr. Apley's needs, and those of others. The words "promethean" and "epimethean" are euphonious, they suit the desired meaning, and they have no taint of that hybrid origin which has kindled so much etymological flame.

Department of Medicine,
The Royal Infirmary, Manchester, 13.

D. A. K. BLACK.

SIR,—"Prespective" seems right. Præspective might be better, but we have "predestined" and "prescribed" and recently "pre-selective"; and American "pediatricians" would certainly omit the "a."

Bristol.

ALLAN MCFARLAN.

SIR,—Dr. Apley's difficulty seems to have been answered this very week by no less an authority on the

1. *Lancet*, 1953, 1, 305.

use of words than Sir Winston Churchill. In a reply to Mr. Shinwell on a question concerning the atom bomb, he said: "I endeavour to allow my thoughts to play in retrospect as well as in prospect over all my acts."

Perhaps that too gives us a clue to the approach we should adopt to both forms of research.

Thornton Heath,
Surrey.

S. G. HAMILTON.

PATHOLOGISTS AND PNEUMOCONIOSIS

SIR,—I hate prolonging this already rather long correspondence any further, but I find Dr. Fletcher really hard to please.

Last time (March 20) he blamed the absence of a pathological classification for missed post-mortem diagnoses, and he dismissed the pathologists' approach to the problems involved for that reason. This time (April 3) he finds that the greatest source of sampling error in post-mortem statistics is the failure of all possible cases to reach the necropsy table.

As far as the intra-vitam certified cases are concerned, the necropsy is obligatory by law and the procedure is foolproof. As for the non-certified cases, the times when a coalminer would hesitate to mention his chest troubles for fear of losing his job are long gone. At present, it would mean a failure on the part of the coalminer, his dependants, his trade union, and—dare I mention it?—his doctor if the case is not fully investigated before or at least after death. The first two parties would be activated by the prospect of a pension and the other two by the wish to do their job; all that is required is a phone call to the coroner.

In these circumstances, while I agree that even this quadruple failure may happen as an occasional and deplorable occurrence, I feel it is rather hard of Dr. Fletcher to consider that it does so frequently. His statement implies a censure on G.P.s in colliery practices, and I doubt that they deserve it.

Dr. Fletcher mentions the concept of "pulmonary dust disease." I agree with him there, but, as long as the present Acts are based on a different definition, such considerations, valuable though they are, cannot form the basis of our actions.

Dr. Joules (March 27) tells me that at the necropsies of the 4500 fog victims in London in December, 1952, no fog was present in the lungs. While I have no wish to dispute this, I wish to point out that, according to the U.S. Government Report on the Donora fog disaster in 1948, sulphur compounds were found in the lungs of the victims at necropsy. So on that occasion at least, fog was present in the lungs.

Finally, in my original letter I asked for coöperation from other practitioners working in coalmining areas. I repeat my plea, for I feel that progress in the research into industrial dust disease will not come from recriminations and fault findings, but from coöperation and mutual assistance.

Abertillery, Monmouthshire.

K. TRIGER.

CONTROL OF DENTAL CARIES

SIR,—I would like to add a few remarks about the control of dental caries, particularly since Dr. Burgess and Dr. Burton, in their article of April 10, discuss "Beginning at the Beginning." Although prevention does not apparently concern the G.P. directly, the principles of prevention are very much interwoven with many aspects of his work.

An excessive intake of carbohydrate is blamed for the production of caries, and I believe rightly so; but, in addition to the local effects, it may affect the "protein pool" of the body and incidentally the "organic turnover" of not only the teeth but other structures.

In the prevention of caries the introduction of one factor, say fluorine, may raise the level of resistance to a satisfactory

height, but we do not know what it may do to resistance to other types of bacteriological invasion or equivalent forms of stress.

By aiming at calcium intake, have we pinpointed the mineral constituent, and by the recommendation of milk have we given an impression which overemphasises it as a "good food"?

Coming back to the carbohydrate intake, there are several factors involved: (a) the family feeding pattern; (b) the generally accepted habits of the circle in which we move; (c) the difficulty of restricting sweet consumption in one's own children without making them feel too different from their friends; (d) the feeding difficulties of early life and the easing of tension when sweeter foods are given because "after all a child as active as that must have something to keep going"; (e) an understanding of diet, especially from the point of view of breaking the habits produced by temporary stresses. Finally, the conversion of "dietetic hyperinsulinism" and its cravings to a normal metabolic pattern is probably not the least of the problems.

These remarks are not levelled in criticism; I am merely trying to show, if possible, how wide the problem of dental caries is.

Clapham, Yorkshire.

J. A. FARRER.

SAFER HYPOTENSION

SIR,—Much interest has been focused in recent months not only on the advantages but on the dangers of the use of hypotensive techniques in surgery.¹⁻³ With the methonium compounds the degree and duration of the blood-pressure falls are often variable and not always easily reversed. It would seem from reports on the use of 'Arfonad'^{4,5} that, because of its short action, this agent makes the use of hypotension a more controllable and hence a safer procedure. In our opinion, and that of others,¹ the safety of this technique can be further increased by combining it with hypothermia, thereby lowering the metabolism and oxygen requirements of the brain.

We have used the combination of hypothermia and hypotension (with arfonad) in a small series of selected neurosurgical procedures, and the results have been very satisfactory. These were operations for aneurysms and vascular tumours which would have proved difficult, if not impossible, with orthodox methods of anaesthesia. Hypothermia, and the drugs used in its production, will lower the systolic blood-pressure to about 100 mm. Hg, this fall being reinforced when required by the use of arfonad.

Hypothermia is produced by surface cooling using a modification of a technique already described.⁶ All adult patients are given 50 mg. of chlorpromazine by deep intramuscular injection about one hour before anaesthesia is induced. This is combined with pethidine and/or promethazine, depending on the degree of consciousness. On arrival in the anaesthetic room, patients are prepared for operation in the usual manner, very small doses of thiopentone being required. Surface cooling with ice bags is then commenced, and any tendency to vasoconstriction, as shown by a sharp fall in skin-temperature, is overcome by the intravenous administration of further doses of chlorpromazine. The largest dose of this drug that we have used to date is 95 mg.

The light anaesthesia maintained with nitrous oxide-oxygen, together with the chlorpromazine, with or without trichloroethylene, has completely eliminated shivering. With this technique it has always been possible to reduce the rectal temperature to 32°C (89.6°F) within one hour of the first application of ice. All active cooling is then stopped and the temperature falls slowly during the operation to about 30°C (86°F).

1. See *Brit. med. J.* Feb. 6, 1954, p. 324.
2. Davison, M. H. A. *Anaesthesia*, 1953, 8, 255.
3. See *Ibid.*, p. 263.
4. Anderson, S., McKissock, W. *Lancet*, 1953, ii, 754.
5. Kilduff, C. J. *Ibid.*, Feb. 13, 1954, p. 337; Scurr, C. F., Wyman, J. B. *Ibid.*, p. 338.
6. Dundee, J. W., Gray, T. C., Mesham, P. R., Scott, W. E. B. *Brit. med. J.* 1953, ii, 1237.

The arfonad is given by continuous infusion of a 0.1% solution, similar to the method of Scurr and Wyman.⁵ A very slight head-up tilt (5°-10°) is used during operation.

The outstanding difference between this technique and those previously described is the small amounts of arfonad required to reduce the systolic blood-pressure to 60 to 70 mm. Hg. A drip rate of 5 to 10 per minute is rarely exceeded, 100 to 150 mg. of arfonad being the usual requirements for 3 to 4 hour operations. In one case a "pressure floor" of 70 mm. Hg systolic could not be passed by increasing the drip rate, and this only delayed the recovery. Tachycardia has not been observed in any case, presumably because of the hypothermia.

It is our aim to return the systolic blood-pressure to 90 to 100 mm. Hg before closure of the dura mater, and in this we have always succeeded. A rise of 15-20 mm. Hg occurred within 5 to 10 minutes of stopping the arfonad. Irrespective of the degree of bleeding, a bottle of blood or 'Intradex' is given quickly at this stage, resulting in a similar rise in the pressure. In the one instance where these measures were not sufficient, a 1:1,000,000 l-noradrenaline drip quickly rectified matters, and it was discontinued after 20 minutes.

No active attempts are made to restore the normal body-temperature at the end of the operation, and temperatures of 35°-37°C are attained within 6 to 8 hours, with a gradual return of normal blood-pressure.

Reduction in bleeding resulting from controlled hypotension has opened up new fields in the realms of plastic, E.N.T., and neurosurgery. In every case, however, one has to weigh the dangers of severe bleeding at operation and those which may result from the prolonged period of low blood-pressure. We feel that while arfonad is probably the greatest advance that has been made since the technique was introduced, its combination with hypothermia should rob controlled hypotension of many of its undesirable sequelæ.

SHOE DESIGN AND THE GREAT TOE

SIR,—May I, an outsider, join your discussion of shoe design?

I take the view that the normal environment of the foot is unshod on a yielding and uneven surface (sand, earth, &c.), so I have designed a shoe that will simulate this environment as closely as possible. First, a plaster impression of the foot is taken, with the foot bearing no weight but in a weight-bearing attitude, and from this a plaster model is made. The shoe is moulded directly on this model, the hypothesis being that the foot should design the shoe, not that the shoe should design and deform the foot.

The outside of the shoe is made of soft leather with a flexible rubber sole. The inside will fit every curve of the dorsum and the plantar surface of the foot. The insole will be rounded at the heel and metatarsal area, built up to the long arch, and even built up under the toes to aid them in their grasping action and also prevent the foot from gliding forward.

In the moulded shoe the entire plantar surface of the foot will help carry the body-weight: heel, long arch, five metatarsal heads, five toes, and even the webbed areas under the toes.

In the conventional woman's shoe the body-weight is carried by the base of the heel and the second, third, and fourth metatarsal heads. Because of the pointed shoe, the great toe is forced medially during walking, causing all the weight to be carried on the middle metatarsal heads with the subsequent formation of corns and callosities and deformities of the toes—the most serious of which is hallux valgus. In men, where the shoe is wider, but not wide enough, the most common condition is the callosity under the first and fifth metatarsal heads.

I have observed excellent results with shoes made in this way. Corns and callosities have completely disappeared within six to eight weeks. Within a year after wearing the shoes, many toe deformities begin to correct themselves; but it is too early to say what will happen to chronic deformities. At all events, pain is relieved immediately.

Philadelphia, U.S.A.

H. T. LOVITZ.

SIR,—I was interested to read in your issue of March 27 a letter from Dr. Haines and Mr. McDougall. But I must disagree with their statement that, although flat shoes have become popular since the war, "they seldom appear in fashion magazines." My own company, in common with other leading manufacturers of flat shoes, publicise them extensively in fashion magazines and women's magazines. We also find that the fashion magazines often discuss our flat shoes in their editorial columns.

Selby Shoes Limited,
London, W.1.

J. F. H. HINTON.

AUTOHÆMOTHERAPY IN HERPES ZOSTER

SIR,—Two leading textbooks say of herpes zoster: "The course of the eruption is uninfluenced by treatment."¹

"Nothing will check the disease."²

Yet this is a severe affliction, which causes long-lasting neuritis and pain in the affected part, and, if it attacks the cornea, the result may even be loss of the eye.

In the past forty years I have treated many cases of herpes zoster by intramuscular injection of the patient's own blood, and when this treatment has been started in the first two days it has always checked the disease. The most dramatic improvement has been in herpes of the eye, and I believe that I have saved many eyes.

Using a 5-ml. syringe, 5 ml. of blood is withdrawn from a vein in the bend of the elbow and is injected into the deltoid muscle of the same arm. It is as well to repeat this injection of the patient's own blood the next day. Of course, in addition, the pain-relieving remedies should be used—i.e., aspirin, phenacetin, codeine, or pethidine—and an aperient should be used to counteract the constipation they cause.

This autohæmotherapy is simple and without risk. It should be given as soon as the illness is recognised. Unfortunately it is not much good three weeks later when the neuralgic pains cause so much distress.

London, W.1.

V. NESFIELD.

3-D. IN MEDICAL ILLUSTRATION

SIR,—In your issue of April 10, you note (p. 787) an article of Dr. J. G. Robson and myself which appeared in *Anæsthesia* and which was illustrated by stereoscopic anaglyphs.

In his editorial comment the editor of *Anæsthesia* expressed the belief that "it is the first time that this type of stereogram has been used in a medical journal." In this comment he may strictly be correct, since I believe that there are several processes for producing these stereograms, though the final result of them all appears rather similar. Your note is a little more general however, and I think it would be unfair if your readers gained the impression that this is the first occasion on which stereograms by any anaglyphic procedure had appeared in a medical journal, because in a supplement to the November, 1953, issue of *Medicine Illustrated* there appeared some anaglyphs by Mr. P. Hennessy and Mr. J. Hardman.

This sort of confusion readily arises when a technique is new, and I apologise for occupying your space with

1. Conybeare, J., Mann, W. N. *Textbook of Medicine*. Edinburgh, 1952.

2. *Taylor's Practice of Medicine*. London, 1936; p. 1000.

a rather minor matter. It would, however, be a pity, through misunderstanding, to cause irritation to those concerned.

Department of Anaesthetics,
The Medical School,
Newcastle upon Tyne.

E. A. PASK.

BILIGRAFIN IN CHOLECYSTOGRAPHY

SIR,—I have read the annotation on 'Biligrafin' in your issue of April 17 with interest. I am at present working with samples of biligrafin kindly supplied by Messrs. Schering A.G. of Berlin.

I have found the substance entirely satisfactory, fulfilling all the claims mentioned in your annotation, save that I now have to record a severe reaction. This occurred in an apparently healthy man of 72 years, suffering only from suspected gall-bladder disease and not at that time jaundiced.

The injection of biligrafin was slowly given intravenously. After 30 ml. had been injected the patient complained of a pricking sensation in the anus, and injection was immediately discontinued. Four minutes later, he suddenly lost consciousness. He was pulseless with stertorous breathing, pallid complexion, cyanosis of the extremities, and an imperceptible radial pulse. There was urinary incontinence. Resuscitation was achieved with the aid of continuous oxygen, injections of nikethamide ('Coramine'), antazoline ('Antistin'), and adrenaline. After 15 minutes, the patient regained consciousness and his subsequent recovery was uneventful.

One previous case of collapse is quoted by Hornykiwytch and Stender¹ but no details are given.

Cambridge.

M. W. P. WARD.

THE BOMBS

SIR,—Many people will be grateful for your leading article last week. The established facts about the bomb reduce to tragic absurdity the arguments of statesmen and military leaders that the world must, to preserve peace, devote itself to preparing for war. Homicide on a scale approaching this has hitherto been possible only when millions of people have been persuaded that their duty or interest lay in supporting war, and the act of war demanded that these millions should throw themselves into movement. The hydrogen bomb makes it possible, for the first time in the history of the world, for a few men in positions of power to dispense with the consent and active support of their people in waging war. Neither fear of retaliation nor any moral considerations will restrain the desperate. Indeed, the decision to use the first atom bomb appeared to many people then, and to far more since, to have no moral justification.

You praise our profession for the part some members of it have played in urging upon the world the paramount need for humanity to outlaw the mass murder which is at present condoned in war. Professor Haddow, to whose courageous letter in the *Times* you call attention, has suggested that scientists all over the world, profiting by the international status of science, should meet to appraise the human situation created by the existence of the hydrogen bomb, and set themselves to devise policies to prevent its manufacture. This is obviously a proposal of great value and I suggest that all of us have a duty to obtain for it the support of our professional organisations.

I should like to remind my colleagues that there is an organisation of doctors in this country which exists to study this great dilemma—namely, the Medical Association for Prevention of War. Under the auspices of this association, Prof. C. F. Powell, F.R.S., and Dr. Comfort will be addressing a meeting on the hydrogen bomb at Friends' House, Euston Road, London, N.W.1, at 7.30 p.m. on Wednesday, April 28.

Bickley, Kent.

DUNCAN LEYS.

1. Hornykiwytch, T., Stender, H. S. *Fortschr. Röntgenstr.* 1953, 79, 293.

SIR,—There is one aspect of the hydrogen bomb which few medical men will fail to recognise—it is the mental patient's weapon *par excellence*. Atomic research in the United States (we cannot speak for Russia, which keeps its own counsel) has long since passed from the sphere of weapon research into that of abnormal psychology. In such a context, it is hard to place confidence in the consideration that no sane authority will destroy itself. The sane man may say "If that man hits me I will hit him": the sane but cruel man, "If that man hits me, I will kill him and his whole family." But there is a recognisable and pathognomonic ring about the proposition "If that man hits me, I will burn down the house and kill us both." It leads naturally on to the further proposition "That man is going to hit me: I will burn down the house and kill us both to forestall him." To say that the policy of "massive retaliation" already exemplifies this state of mind is a medical, not a political, judgment—to those who remember the utterances which came from a certain burning Chancellery, the cravings for *Götterdämmerung*, for the deliberate mistake, for the opportunity to smash everything, are dangerous and present realities in both medicine and politics.

The paranoia of nations, being shared out, as it were, between a large number of normal, and a few abnormal, but directing, individuals is always diluted with normality, with some humane responses to which we can appeal. In both the major atomic powers today, it is largely so diluted. From the psychological standpoint, the traditional rigidity of Russia seems less menacing today, and in the context of this weapon, than the traditional hysteria of the United States. Both powers are subject to the pressure of world public opinion. I believe that a forthright and total renunciation of such weapons by our own country would have great psychotherapeutic value; it might help us to avoid the paralysis of public attitudes by guilt-feelings over the last atom bombs, which has affected the United States, and it would enormously raise our domestic morale and our external moral authority. This is a case where British opinion might without arrogance act as therapist. In spite of the propaganda of malicious people, we have no great fear or hatred of either side. We have few McCarthys or Berias to handicap us. The responsibility of reconciliation is one which we can all accept, and which the medical profession should be proud to lead. It is our only hope, after all, of surviving the century.

Loughton, Essex.

ALEX COMFORT.

Parliament

Fewer Dentures

IN the House of Commons on April 15, replying to Mr. R. E. Winterbottom who raised the question of the number of dental technicians, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the Ministry believed there were more of these workers than there was work for them to do. In 1948, 437 people applied for apprenticeships, and in 1949, 1205 people applied. In 1950, when many of these apprentices were not yet trained, 5 million dentures were supplied under the National Health Service. But in 1953 only 2 million dentures were supplied, and she thought that this figure would be the average annual demand for some years. If the service was a success fewer, and not more, technicians would be needed for people would look after their teeth and keep them longer. In the last quarter of 1953, 380,000 dentures were supplied; in the first quarter of 1954, 394,000. The effect of the treatment charges had been a vast increase in conservative work, particularly among children and adolescents. There was no desire to cheese up on this service, but the Minister was convinced that there were enough technicians to deal with the situation. There

were between 200 and 250 technicians employed in the hospitals, and all except about 80 were in the teaching hospitals. At present the Whitley Council was drawing up an apprenticeship scheme for the training provided in hospital and local-authority laboratories.

QUESTION TIME
Hospital Consultants

Mr. A. A. H. MARLOWE asked the Chancellor of the Exchequer what consultations had taken place between the Treasury and the Ministry of Health on the expenses of hospital consultants employed in the National Health Service which were not deductible for income-tax.—Mr. J. A. BOYD-CARPENTER, financial secretary to the Treasury, replied: Hospital consultants are, like other employees, assessable under schedule E, and the same rules for expenses apply to them as to other taxpayers. I see no reason to propose legislation giving them preferential treatment. The general question of what expenses are admissible to such taxpayers is within the terms of reference of the Royal Commission.

Replying to a question, Miss PATRICIA HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, said that the number of consultants employed by regional boards in England and Wales who had transferred from whole-time to part-time service was 42 in 1951, 61 in 1952, and 46 in 1953.

N.H.S. Charges

Replying to questions, Miss HORNSBY-SMITH said that N.H.S. charges were introduced in 1952. The number of prescriptions dispensed by chemists in February, 1954, was 19,203,000, compared with 21,645,000 in February, 1953.

The estimated cost to the Exchequer of dental treatment for these months was £1 million and £800,000 respectively.

Hydrocortisone Supplies

Replying to a question, Miss HORNSBY-SMITH said that production of hydrocortisone in this country started only recently. The supplies now available to hospitals receiving cortisone would be increased as the need arises.

Welfare Food Service

Replying to a question, Major GWILYM LLOYD GEORGE, Minister of Food, said that about 97% of those entitled to obtain milk or 'National Dried Milk' under the welfare foods service did so. The quantities of the vitamin supplements taken up in 1953 expressed as a proportion of the full entitlement were as follows: orange juice 29.4%; cod-liver oil 23.8%; vitamin tablets 32.6%. The percentage of persons who obtained the vitamin supplements was higher than these figures suggested, because many did not take their full entitlement.

Contamination of Citrus Fruits by Thiourea

Mr. JOHN PARKER asked the Minister of Food what action was being taken to safeguard the public from thiourea poisoning in oranges imported from Spain. Major GWILYM LLOYD GEORGE replied: Local authorities in whose areas such oranges have been reported have been approached with a view to their taking appropriate action. As a result they have warned merchants against further importation. The Spanish authorities have also warned all their fruit-inspection offices that the complete prohibition of the export of such oranges to Great Britain must be strictly enforced.

Public Health

Poliomyelitis in Denmark

Denmark had a formidable outbreak of poliomyelitis in 1952, when the attack-rate of the paralytic form in Copenhagen was 106 per 100,000 population. Hamtoft¹ has now compared the experience in 1953 with that in the preceding year.²

The epidemic of 1953 was surpassed only by those of 1952, 1944, and 1934. Between the outbreaks of 1952 and 1953 notifications fell to the lowest level about May 1,

which showed the greatest number of cases in 1952 practically escaped the epidemic in 1953, while the counties not stricken by the epidemic in 1952 showed large numbers of cases in 1953."

England and Wales in 1953

The Registrar-General publishes this week further details³ for England and Wales in 1953; he had already given some provisional figures in an earlier return.⁴ The estimated home population of England and Wales at Dec. 31 was 44,166,000—an increase of about 420,000 since the census in April, 1951. On the basis of the death-rates for 1952, it is reckoned that the expectation of life of a boy at birth is now 67.06 years and of a girl 72.35 years. On the basis of the death-rates for the years 1901-10, the expectations were 48.53 and 52.38 respectively. In an analysis of the causes of death, it is noted that the number of deaths from accidental poisoning continues to rise, reaching 659 in the first nine months of 1953, compared with 586 during the corresponding nine months of 1952. The number of suicides increased in the same period from 3299 to 3541. A comparison of death-rates of children under one year of age in the September quarter of 1953 shows that the rate of 22 per 1000 related live births compared with the following rates in other countries: Netherlands 19, Australia 25, U.S.A. 26, Scotland 28, France 33, Italy 64.

The School Lavatory

In his 1953 report to the City of Oxford Education Committee, Dr. J. F. Warin comments on the continuing failure of some of the schools to remedy obvious defects in sanitary arrangements. Provision of bolts on lavatory doors, lavatory chains, and brackets for toilet-paper and a supply of paper, cost little and are too often lacking. "The key personnel in this matter are the head teacher and the caretaker." Dr. Warin again emphasises the need for schools to play their part in training children in cleanly habits—for which a sufficiency of properly equipped lavatories (with wash-basins) is essential. "The experience of most head teachers has been that provided conveniences are kept in good order and supplied with toilet paper on proper brackets then care is exercised by the children."

POLIOMYELITIS IN DENMARK, 1952 AND 1953

Area	January, 1952, to April, 1953				May, 1953, to December, 1953				1952 + 1953: paralytic cases per 100,000 population
	Paralytic cases		Non-paralytic cases		Paralytic cases		Non-paralytic cases		
	Total	Per 100,000 population	Total	Per 100,000 population	Total	Per 100,000 population	Total	Per 100,000 population	
Copenhagen, metropolitan area ..	1289	106	1831	134	53	4	147	12	110
Rest of country ..	1271	41	1694	55	521	17	872	21	58
Total Denmark ..	2560	58	3325	76	574	13	819	19	71

and for the purpose of assessing the two outbreaks this date is taken as the dividing-point. The most striking difference between the two epidemics is in the relative distribution of cases between Copenhagen and the rest of the country, shown in the accompanying table. Whereas in 1952-53 the attack-rate of paralytic poliomyelitis was nearly three times greater in Copenhagen than in the rest of the country, in May to December, 1953, the rate in Copenhagen was only a quarter of that in the rest of the country. Furthermore, "The counties

Notes and News

A CANADIAN COLLEGE OF GENERAL PRACTICE

LAST year, at a meeting of the Canadian Medical Association, it was decided to set up a college of general practice "within Canadian organised medicine" with the following aims:

- To establish an academic body with broad educational aims.
- To arrange for undergraduate teaching by and for general practitioners.
- To arrange for the presentation of postgraduate education for general practitioners.
- To arrange for research in general practice.
- To arrange for publication of original articles by general practitioners.
- To arrange for hospital staff appointments for general practitioners.
- To provide suitable recognition to members in the field of general practice.
- To do all things necessary to maintain a high standard in general practice.

The college will be officially inaugurated at the meeting of the association at Vancouver in June. Applications for membership should be sent to the College of General Practice of Canada, 244, St. George Street, Toronto 5, Ontario.

DANISH BULLETIN

Denmark, with just over four million inhabitants, makes a contribution to medical knowledge out of proportion to its size; but, since the Danish language is understood by less than 1% of the people of the world, the extent of this contribution may not always be apparent. Accordingly a new monthly bulletin in English,¹ sponsored by the Danish Medical Association, medical schools, and national health service, should prove especially valuable. Its purpose is to survey Danish medicine by means of original articles, short communications, and annotations; and an article in the first issue is referred to in our public-health section this week. The bulletin will be sent without charge to subscribers to *Ugeskrift for Læger* and, on request, to medical institutions.

RENÉ SAND MEMORIAL

THE International Conference of Social Work is opening a memorial fund to commemorate the life and work of Prof. René Sand, its founder, who died in 1953.

Professor Sand, who held the chair of social medicine in the Free University of Brussels, was a former secretary-general of the League of Red Cross Societies, and had also shared in the foundation of the World Health Organisation. He was at the time of his death president of the International Hospital Federation.

It is proposed that the memorial fund shall be used to award a biennial prize for "outstanding service in social welfare or social medicine." Contributions may be sent to Mr. G. E. Haynes, the president of the conference, 26, Bedford Square, London, W.C.1, or to the secretaries of the national committees of the conference.

THE UNMARRIED MOTHER

A PAMPHLET by a Roman Catholic social worker² gives a brief but comprehensive survey of the social and moral causes of illegitimacy and the measures for prevention and alleviation of the suffering caused to women and their illegitimate babies. Written from the Roman Catholic viewpoint, its approach is sensible and practical, and due tribute is given to the work of other bodies.

University of London

On March 19 the Graham medal was presented to Prof. G. R. Cameron, F.R.S.

University of Glasgow

On June 16 the honorary degree of LL.D. will be conferred on Prof. J. H. Dible, Sir John McNee, and Prof. G. I. Strachan.

Royal College of Physicians of London

Dr. J. Forest Smith will deliver the Croonian lectures on Tuesdays, May 4 and 11, at the college, Pall Mall East, S.W.1, at 5 P.M. His subject will be Nutrition and Child Health.

1. Danish Medical Bulletin. Subscription £1, \$3, or equivalent; payable to Ejnar Munksgaard, 6, Nørregade, Copenhagen.
2. The Unmarried Mother and her Child, by MARY WALSH. Catholic Truth Society, 38, Eccleston Square, London, S.W.1. Pp. 21. 4d.

National University of Ireland

Mr. Patrick FitzGerald has been appointed associate professor of surgery at University College, Dublin. Dr. Paul Cannon has been appointed professor of physiology, and Dr. Fergus O'Rourke professor of zoology, at University College, Cork.

The degree of M.D. has been awarded to A. P. Barry.

Royal College of Obstetricians and Gynaecologists

On Friday, May 21, at 5 P.M., at the college, 58, Queen Anne Street, London, W.1, Mr. Ian Donald will deliver the Blair-Bell lecture. He is to speak on Atelectasis Neonatorum.

Institute of Dermatology

Two semi-permanent exhibitions are being shown at the institute during the summer course. The first, from May 3 to 22, by Dr. J. O. Oliver, will be on Animal Parasites in Diseases of the Skin.

Royal Sanitary Institute

The annual health congress of this institute is to be held at Scarborough from April 27 to 30, under the presidency of the Earl of Feversham.

Diabetic Association

The scientific meeting of this association will be held at University College Hospital Medical School, Gower Street, London, W.C.1, on July 16 and 17. On July 16, at 2.30 P.M., Dr. K. Hallas-Møller will deliver the Banting lecture, on the New Insulins. Those who wish to read communications should write to the association, 152, Harley Street, London, W.1.

Where to Practise

The Medical Practices Committee have revised the classifications of areas for England and Wales. A doctor who is proposing to enter practice should apply for up-to-date information from the executive council of the district before taking steps to secure surgery and waiting-room accommodation.

Medical Art Society

This society is holding an exhibition at Walker's Galleries 118, New Bond Street, London, W.1. Until May 8 it will be open from 10 A.M. to 5 P.M. (Saturdays 10 A.M. to 1 P.M.).

Association of Social Workers

This association is holding a course at County Hall, Westminster Bridge, London, S.E.1, on May 28, and 29, on the Social Worker and the Group Approach. The first session will take place at 6 P.M. on Friday, the 28th. Further particulars may be had from the conference secretary, Silverbeck, Stanwell Moor, Middlesex.

National Society of Children's Nurseries

A conference on the Needs of the Family in a Changing Society is to be held on Friday, May 7, at 10.30 A.M., at County Hall, Westminster Bridge, London, S.E.1. The speakers will include Prof. Fraser Brockington, Dr. Alice Stewart, and Dr. D. W. Winnicott. Further particulars may be had from the secretary of the N.S.C.N., 45, Russell Square, W.C.1.

Prizes for Clinical Research

A year ago the South West Metropolitan Regional Hospital Board decided to offer prizes to encourage "minor items of clinical research" (see *Lancet*, 1953, i, 249). The following awards for 1953 have been announced:

Up to 3 prizes of £100 each for consultants and S.H.M.O.s.—Dr. M. Hamilton, formerly psychiatrist (S.H.M.O.), Springfield Hospital (treatment of paranoid psychoses); Dr. A. M. Read, assistant chest physician, Portsmouth chest clinic (ventilatory defect following treatment by artificial pneumothorax); Dr. D. A. J. Williamson, consultant paediatrician, Southampton, Winchester, and Treloar groups (epidemiological and clinical survey of ascariasis).

Up to 3 prizes of £100 each for senior registrars, registrars, etc.—Mr. G. Bennett, D.O.M.S., senior registrar, Southampton Eye Hospital (aetiology and surgical treatment of glaucoma); Dr. G. S. Crockett, senior medical registrar, Lambeth Hospital (measurement of pulse-wave velocity in the human subject); Dr. C. Donovan, formerly psychiatric registrar, St. James' Hospital, Portsmouth (plasma-ascorbic-acid response in psychotics).

Up to 3 prizes of £100 each for house-officers.—Mr. A. O. Wilson, F.R.C.S., formerly house-surgeon, Royal Hants County Hospital (absence of fluid and electrolyte disturbances in patients undergoing partial gastrectomy and given limited amounts of fluid intravenously after operation); Mr. M. Wynyard, F.R.C.S., formerly house-surgeon, St. James' Hospital, Balham (anatomy of the big toe with regard to the long saphenous nerve).

A similar competition is being held this year and particulars will be sent to group medical committees in the region.

Medical Association for the Prevention of War

In collaboration with Science for Peace, this association has arranged a meeting on the Hydrogen Bomb. This will be held on Wednesday, April 28, at 7.30 p.m. at Friends' House, Euston Road, N.W.1, and the speakers will be Prof. C. F. Powell, F.R.S., of Bristol, and Dr. Alex Comfort. The address of the association is 291, Burntwood Lane, S.W.17.

Davidson Clinic, Edinburgh

A summer school on Conscience and Psychology is to be held at the clinic, 58, Dalkeith Road, Edinburgh, 9, from July 28 to Aug. 3.

Research Board for the Correlation of Medical Science and Physical Education

This board has given the William Hyde award (£300) for 1952 to Miss P. C. Colson, the general secretary to the Central Council of Physical Recreation.

Sister Kenny's Contribution to the Treatment of Poliomyelitis

Dr. M. E. Knapp, of the Elizabeth Kenny Institute, Minneapolis, will speak on this subject at Queen Mary's Hospital for Children, Carshalton, on Monday, May 10, at 5 P.M. Further particulars will be found in our advertisement columns.

Institute of Hospital Administrators

The annual conference of this institute is to be held from May 6 to 8 at Oxford. The subjects chosen for discussion are: The Patient as the Centre of the Hospital; Coöperation with other Services in Treating the Patient; and Patients' Complaints and Criticisms. Further particulars may be had from the secretary of the institute, 75, Portland Place, London, W.1.

French Documentary Film on Cancer

Sir Stanford Cade will introduce this film when it is shown at the Institut Français, 15, Queensberry Place, London, S.W.7, on Wednesday, May 12, at 8 P.M.

The film was made by Etudes Cinématographiques, under the direction of Dr. Pierre Thevenard of the Institut Pasteur, as part of the anti-cancer campaign. The 13 sections include cartoons, laboratory work with animals, acted scenes, and interviews with successfully treated patients. Tickets may be had from the scientific office of the French Embassy, 22, Wilton Crescent, S.W.1.

Association Internationale pour l'Étude des Bronches

The fourth congress of this association will be held at Geneva on June 5 and 6, under the presidency of Prof. André Montandon. The subjects chosen for discussion are: Blood-supply of the Bronchi, Classification of Bronchial Adenomas, and Surgical Treatment of Bronchial Dilatation. Further particulars may be had from the secretary of the congress, Clinique Universitaire d'Oto-Rhino-Laryngologie, Hôpital Cantonal, Geneva, Switzerland.

Human Milk Bureau.—With the help of Queen Charlotte's Maternity Hospital, London, Camera Talks (23, Denmark Place, W.C.2) have produced a filmstrip illustrating the work of the hospital's milk bureau.

Appointments

- FIELD, C. M. B., M.D. Belf., M.R.C.P., D.C.H.: consultant pædiatrician, South Belfast H.M.C.
- KLEIN, DOROTHY, M.B. Edin., D.OBST.: asst. M.O., Southend-on-Sea.
- RICHARDSON, J. D., M.D. Lond., D.P.M.: consultant children's psychiatrist, South Lincolnshire.
- ROONEY, JEAN F. W., M.B. Dubl., D.C.H.: asst. school M.O., Bedale & Northallerton area.
- SEWELL, T. P., M.D. Manc., D.P.H.: deputy county M.O.H. and deputy school M.O., Lancashire.
- WATSON, JEAN M. I., M.B. Leeds, D.OBST.: asst. maternity and child welfare M.O. and school M.O., Derbyshire.
- WESTON, J. W., M.R.C.S., D.T.M.&H.: asst. pathologist (S.H.M.O.), Halifax hospitals group.
- YOUNG, R. J., M.D. Belf., M.R.C.P.: consultant pædiatrician, Londonderry and north west area of Northern Ireland.

Sheffield Regional Hospital Board:

- BATES, T. J. N., B.A., M.B. Edin., D.P.M.: senior asst. psychiatrist, Saxondale Hospital, Radcliffe-on-Trent.
- CONN, HERBERT, M.D. Berlin: senior asst. psychiatrist, Kingsway Hospital, Derby.
- LUMLEY, W. T. C., M.B. Lond., D.O.M.S.: asst. ophthalmologist, Chesterfield Royal Hospital and associated school ophthalmic clinics.
- MONYPENNY, ISABELLE G., M.R.C.S., F.F.A.R.C.S., D.A.: consultant anaesthetist, Sheffield R.H.B. and United Sheffield hospitals.
- OSTROWSKI, T. M.: M.B. Polish School of Medicine, Edinburgh: senior casualty officer, Beckett Hospital, Barnsley.

Diary of the Week

APRIL 25 TO MAY 1

Monday, 26th

- ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Section of Odontology.* Mr. R. L. Hartles, B.S.C.: Carbohydrate Degradation in the Mouth.
- HUNTERIAN SOCIETY
7.30 P.M. (Talbot Restaurant, London Wall, E.C.2.) Mr. W. R. Le Fanu, M.A.: Hunter-Baillie Manuscripts.
- MANCHESTER MEDICAL SOCIETY
9 P.M. (Medical School, University of Manchester.) *Section of General Practice.* Dr. W. E. C. Thomas: Obstetrics in General Practice.

Tuesday, 27th

- ROYAL SOCIETY OF MEDICINE
8 P.M. *Section of Medicine.* Prof. Max Rosenheim, Dr. S. J. de Navasquez, Dr. J. M. Stansfeld: Chronic Pyelonephritis.
- ROYAL STATISTICAL SOCIETY
6 P.M. (Westminster Medical School, Horseferry Road, S.W.1.) *Study Circle on Medical Statistics.* Discussion of Working Party Report on Assessment of Need for Clinical Services.
- SOCIETY FOR ENDOCRINOLOGY
5.15 P.M. (1, Wimpole Street, W.1.) Dr. Gregory Pincus: Pathways of Steroid Synthesis in Animal Organism.

Wednesday, 28th

- RENAL ASSOCIATION
4.30 P.M. (41, Portland Place, W.1.) Mr. I. H. Griffiths: Renal Arteriography. Dr. Robert Gaunt: Studies on Experimental "Eclampsia-like" Syndrome.

Thursday, 29th

- ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. I. P. Todd: Elective Surgery in Management of Diverticulitis of Colon. (Hunterian lecture.)
- UNIVERSITY OF LONDON
5 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Dr. E. L. French (Melbourne): Epidemiological Aspects of Murray Valley Encephalitis.
- BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, W.1
8 P.M. Prof. J. K. Robertson, F.R.S.C.: An Experiment in Medical Education.
- INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY, 330, Gray's Inn Road, W.C.1
5.30 P.M. Prof. F. C. Ormerod: Aspects of Sinusitis.
- INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
5.30 P.M. Dr. Pincus: Steroids in Ageing.
- LONDON JEWISH HOSPITAL MEDICAL SOCIETY
8.30 P.M. (11, Chandos Street, W.1.) That Quackery Plays a Useful Part in Medicine Today. For: Dr. M. Marcus, Dr. S. H. Chazen. Against: Dr. D. Preiskel, Mr. I. Preiskel.
- MANCHESTER MEDICAL SOCIETY
4 P.M. Prof. Bruce T. Mayes (Sydney): Could Eclampsia Disappear?
- UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Mr. W. M. Dennison: Advances in Surgery of Infancy and Childhood.

Friday, 30th

- ROYAL SOCIETY OF MEDICINE
4.30 P.M. *Section of Epidemiology and Preventive Medicine.* Dr. John Gordon (Harvard): Epidemiologic Method in Modern Perspective.
- 8 P.M. *Section of Radiology.* Dr. E. W. Emery: Three Years' Use of a Cobalt Unit. Dr. D. Verel: Radioactive Phosphorus in Treatment of Polycythaemia Rubra Vera. Dr. F. E. Neal: Radioactive Phosphorus in Treatment of Fungoides.
- FACULTY OF RADIOLOGISTS
4 P.M. (Royal College of Surgeons, Lincoln's Inn Fields, W.C.2.) Prof. D. W. Smithers: Rotation Therapy.
- POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
2 P.M. Prof. A. G. R. Lowdon: Surgical Management of Intestinal Obstruction.
- 4 P.M. Dr. J. E. Caughey (New Zealand): Hypopituitarism.
- INSTITUTE OF LARYNGOLOGY AND OTOTOLOGY
3.30 P.M. Mr. W. D. Doey: Indications for Tonsillectomy.
- MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, W.1
7.30 P.M. Dr. Neville Mascal: *Trichomonas vaginalis.* (Presidential address.)

Births, Marriages, and Deaths

BIRTHS

- CHALMERS.—On April 16, at St. David's Hospital, Cardiff, to Doreen, wife of Dr. T. M. Chalmers—a son.
- GIBSON.—On April 11, at The Shiel, Elgin Road, Weybridge, to Graeme (Galbraith), wife of Dr. Eric Gibson—a son.
- HELSEBY.—On April 12, at Liverpool Maternity Hospital, to Joyce, wife of Raymond Helseby, F.R.C.S.—a daughter.
- MARRIAN.—On April 14, to Biddy Kingsley Pillers, M.B., wife of Denis H. Marrian, Ph.D.—a son.
- THOMAS.—On April 13, at Plas Bowman, Caernarvon, to Nansi Wyn (née Owen), wife of Dr. R. Garym Thomas—a daughter (Amanda Claire).

DIET AND CORONARY DISEASE

J. B. DUGUID

M.D. Aberd.

PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF DURHAM

THE prevalence of coronary thrombosis in recent years has revived interest in the problem of atherosclerosis, and the question of diet as a factor is now receiving a great deal of attention. We have been so impressed by the fact that arterial lesions can be produced in animals by adding cholesterol to their food that we have been disposed to accept the diet hypothesis almost without question, and to infer from it that fatty foods are a cause of coronary disease. Nevertheless the incidence of coronary disease did not seem to decline in this country during the war when our intake of fats was restricted; nor, for that matter, do rabbits with cholesterol lesions tend to die from coronary thrombosis.

In connecting coronary disease with diet we have, I think, oversimplified the problem and taken too much for granted. We have assumed that atherosclerosis represents a single disease process referable to some particular combination of causes, whereas it can now be shown that lesions which go by that name may be the outcome of at least two different processes, with causes which may be quite unrelated to one another. This point, although mentioned as a possibility by White and Ferrero (1949) and by Shillingford (1952), has never been clearly brought out; but unless it is taken into account it is hardly possible to judge where diet may come into the picture. Let us compare, for example, the common form of coronary atherosclerosis with the lesions produced in rabbits by cholesterol feeding. Here I shall repeat, with fresh materials, a demonstration already made (Duguid 1946), because it illustrates certain principles which must be kept clearly in mind.

Coronary Atherosclerosis

The term atherosclerosis refers to a lesion of variable morphology but with two essential characters—namely, fatty change and fibrous thickening of the intima. Sometimes the one character is predominant and sometimes the other; but, in the form of coronary disease with which we are mainly concerned, fibrous thickening is the outstanding one, involving, as it often does,

extreme narrowing of the vessel; and this, as I shall show, is a feature of crucial significance.

When the coronary arteries from cases of long-standing cardiac infarction are examined, occasional examples of canalised thrombi are found in which the affected vessels have two or more channels instead of a single lumen (fig. 1). In these it will often be noted that the fibrous tissue which separates the channels, and which obviously represents organised thrombus, merges with the intima so that the two are indistinguishable. Further, if serial sections are made, a point is reached where the channels unite to form a single lumen; and there it is found that the same organised thrombus extends along the vessel as an inner lining which looks like a fibrous overgrowth of the intima (fig. 2). The thrombus has in fact become part of the intima, and the appearance is that of a thickened artery.

The same thing happens with mural thrombi, which are much commoner than these producing total occlusion. When a mural thrombus forms in an artery it becomes covered with endothelium so that it is incorporated in the vessel wall, with the result that when it is subsequently organised it forms a fibrous thickening of the intima. Since most mural thrombi, before being completely organised, undergo fatty degeneration—sometimes with atheromatous softening and ulceration—they acquire all the characters of atherosclerotic plaques, and we thus learn that some of the lesions we classify as atherosclerosis are in fact organised, or partly organised, mural thrombi. It should of course be understood that most mural thrombi are very small, consisting of no more than microscopic layers of fibrin; but these, when laid down repeatedly one on top of another, can give rise to considerable thickenings of the vessel walls; and this appears to be the sequence of events in many examples of atherosclerosis.

These observations have now been confirmed in one way or another by a number of observers including Harrison (1948), Heard (1952), Geiringer (1951), McLetchie (1952), and Crawford and Levene (1952), and we may safely take it that thrombosis is one factor in the pathogenesis of atherosclerosis. That this has been overlooked in the past is due, I think, largely to the presence of fatty changes. We have not been accustomed to associate these with thrombosis, and their presence has prevented us from recognising the thrombi as such.

Fig. 1.

Canalised left coronary artery from man of 61 who had an infarct of his left ventricle of about 2 years' duration. (Frozen section: Sudan IV and hamalum. $\times 12$.)

In fig. 1 the lumen is occupied by a mass of fibrous tissue which represents an organised thrombus with three separate channels.

In fig. 2, from a point less than 1 mm. distant, the channels have joined to form a single lumen while the thrombus now appears as a fibrous thickening of the wall.

Fig. 2.

Nevertheless fatty changes can be shown to be an almost constant feature of mural thrombi, not only in the arteries but in the heart, including endocardial vegetations, and "in venous thrombi of all kinds," as Cohnheim long ago remarked. The fats, which vary in amount, are presumably derived from the lipids present in the blood when the thrombi are formed.

Cholesterol Sclerosis in Rabbits*

It is generally assumed that arterial thrombosis depends on some underlying lesion of the vessel wall, and a common example in the larger arteries is fatty change. To see whether cholesterol lesions would lead to thrombosis in rabbits Dr. I. Rannie and I have recently repeated the classical feeding experiments and studied the lesions in various stages of development. Rabbits were given 1.5 grammes of cholesterol daily in addition to their ordinary diet and killed after periods ranging from six weeks to more than a year. No mural thrombi were found, but much useful information was obtained from the experiments.

By the end of the sixth week there were changes in the aorta and pulmonary arteries consisting of small deposits of cholesterol-bearing phagocytes (foam cells) in the subendothelial layer of the intima, chiefly near the openings of branches. By the twentieth week the lesions were usually widespread and severe, with great accumulations of foam cells in the intima, often swelling the vessel wall to many times its normal thickness. In the superficial zones the foam cells were deposited in layers of variable thickness, with layers of spindle cells between forming a kind of stroma. In the deeper zones there was often complete disorganisation, the foam cells having disintegrated, leaving atheromatous masses of cholesterol and other fatty debris in their place. In rabbits allowed to survive more than a year the cholesterol had mostly disappeared, leaving dense fibrous thickenings of the intima, so that the condition could with every justification be termed atherosclerosis.

Our findings (Rannie and Duguid 1953) agree in general with those of other observers, but our interpretation embodies a somewhat unorthodox conception. It should be explained that authorities have differed in their views on the process by which cholesterol gets into the walls of the arteries. Duff (1936) and Hueper (1944) believed that it is precipitated from the tissue fluids and taken up by the intimal phagocytes, whilst Altschul (1950) thought that it is absorbed from the circulating blood into the lining endothelial cells and carried by them into the intima. In 1941 Leary put forward the view that in rabbits with hypercholesteræmia foam cells, probably derived from the liver, circulate in the blood and adhere to the arterial walls, which they then actively invade. Our findings supported this in all but the last particular. We saw convincing evidence that the cells in question were present in the blood and adhered to the vessel walls, but we came to the conclusion that instead of invading these, they simply become covered with endothelium and were thus passively incorporated in the same way as mural thrombi. In our view the advanced lesions were formed by successive deposits of foam cells heaped one on top of the other, with occasional layers of endothelial cells laid down between. The atheromatous foci were produced by the breakdown of older and more deeply buried deposits.

The Endothelial Reaction

The important point to be gathered from the foregoing comparative study is that atherosclerosis can arise by two different processes; mural thrombosis on the one hand, and the deposition of lipids, or lipid-bearing cells on the other. This alone should make us cautious in assigning causes. Two further points are I think worth recording although they are contingent on our own

Fig. 3.—Dog's femoral artery into which a silk thread (x) has been inserted and then passed down the lumen. The thread is surrounded by organised thrombus which has been incorporated in the intima to form a fibrous thickening. (Paraffin section: Weigert's elastic tissue stain. $\times 20$.)

interpretation. The first is that in both processes the mechanism, in so far as the arteries are concerned, is the same; solid matter is deposited on the intimal surface and in due course covered with endothelium and incorporated in the intima. That this is a natural reaction of arteries to the presence of solids in their lumen can be shown by inserting a silk thread into the femoral artery of a dog. The thread becomes fixed to the intimal surface with fibrin and the whole mass covered with endothelium and organised, so as to produce a fair imitation of an atherosclerotic nodule (fig. 3) but with silk instead of fat in its centre. The reaction provides an effective means of disposal of undesirable solids from the blood-stream.

The second point is that in none of the processes are the thickenings the result of changes in the original tissues of the vessel wall, as visualised in the current conception of atherosclerosis. All are products of substances deposited on the intimal surface; and thus, if our interpretations are correct, we may take it that atherosclerosis is not a specific disease but merely the common end-result of a number of different pathological processes with different causes.

The Pathogenesis of Human Atherosclerosis

The development of cholesterol lesions has been demonstrated in rabbits, but there is reason to believe that something of the same kind occurs in man, although not necessarily as a result of diet. The "xanthomatous" deposits which appear in the arteries in familial hypercholesteræmia are probably the exact counterpart of the rabbit lesion, but they are too rare to be of much account in the pathology of atherosclerosis. A much commoner lesion of similar morphology is the so-called superficial fatty streaking which occurs in the aortas of young subjects. This consists of deposits of fat-laden cells in the subendothelial layers of the intima, chiefly around the openings of branches, producing an appearance so like the early cholesterol lesions that it is difficult to avoid the conclusion that the same process is involved.

Similar changes are seen in older subjects; but in them they tend to be obscured by advanced atherosclerosis and are therefore difficult to interpret. All observers will agree, however, that in human atherosclerosis changes take place which cannot be put down to thrombosis; and some of them, we may suppose, are of a primary fatty nature, analogous to the cholesterol lesions of rabbits.

Thus we may take it that in man there are two pathogenetically distinct forms of atherosclerosis, and

before arriving at any conclusions as to causation we must have some means of distinguishing them and assessing their relative incidence. Unfortunately most of the lesions we find in human arteries are of long standing, and have passed through a succession of changes which obscures their origin; but sometimes certain distinguishing features persist, and one of them is narrowing.

Arterial Narrowing

The narrowing of arteries in atherosclerosis is a feature which has puzzled observers for the past century. If we accept the long current view that the condition represents a degeneration of the vessel walls, then narrowing seems paradoxical. Arteries are especially constructed to withstand a high internal pressure which is constantly pulsating, and it is their elasticity* which enables them to dilate and recoil again to their original size at each pulse wave, without becoming progressively distended. Any change which weakens them or reduces their elasticity must therefore cause them to give way and dilate rather than become narrowed. Yet in atherosclerosis they are often narrowed almost to the point of occlusion and, as I have reasoned (Duguid 1949), it is difficult to explain this on any other grounds than thrombosis or embolism. When a thrombus forms in an artery it occupies the lumen from the outset and so narrows the blood-stream; and, although in due course it becomes part of the vessel wall, it does so at the expense of the lumen. In this process there is no weakening of the vessel, but merely a reduction of its effective lumen; and, although the thrombus may subsequently shrink, and the lumen become widened again, narrowing must, for a time at least, be the rule.

With the cholesterol lesions it is different, because in them there is no sudden reduction of the lumen but merely a gradual silting up of the walls with foam cells. This must have the effect of reducing their elasticity,

and so we find the rabbit's arteries dilated when they are loaded with cholesterol (fig. 4). An exception to this is sometimes provided when small arteries and arterioles become plugged with foam cells, as may happen in the myocardium. In vessels of small calibre a few such cells are often enough to occlude the lumen and bring about a condition equivalent to embolism, but it is usually in very small branches that this occurs and the effects are negligible. When the larger coronary arteries are the seat of cholesterol deposits, dilatation is the rule; and this is one of the most significant points brought out by the experiments. It has always been assumed that fatty changes lead to narrowing of the arteries by increasing the intima so that it encroaches on the lumen, but the cholesterol lesions show that this is not what happens. Thickening of an artery merely impairs its resilience and leads to dilatation. The only process likely to reduce its lumen is one arising in the lumen itself, such as thrombosis or embolism, and we may therefore take it that, where a coronary artery is narrowed by a fibrous thickening of the intima, thrombosis is the most likely factor.

Narrowing as a Feature in Human Atherosclerosis

Thirty years ago pathologists were inclined to look on atherosclerosis—or atheroma as it was then called—as a minor lesion, universal in old age, and only occasionally attended by serious consequences such as cerebral hemorrhage. In course of time, however, its association with gross myocardial infarction came to be more widely recognised, and today it is regarded as one of the most deadly of lesions, because it leads to narrowing of the coronary arteries with impairment of the cardiac circulation and a tendency to sudden death from thrombosis. Yet these effects are by no means a constant feature of the condition. In old people we often see extreme atherosclerosis with widespread destruction of the arteries but little or no narrowing, and conversely we occasionally find points of extreme narrowing in arteries which are otherwise not very severely affected. There are, in fact, two forms of atherosclerosis—one in which there is narrowing, and which is consequently a highly dangerous condition, and another in which the tendency is rather in the opposite direction.

It would be convenient if we could correlate these two forms with what we have learnt of the pathogenesis, and so infer that all lesions with narrowing were thrombotic, and all others were of a primary fatty nature; but this we cannot do, because thrombotic lesions do not always remain narrowed. Thrombi shrink as they become organised, and arteries which have been narrowed become widened again—sometimes to beyond their original size. Moreover, it is only when thrombi are large in proportion to the vessels they occupy that narrowing is much in evidence. The great majority of mural thrombi consist of no more than microscopic encrustations of fibrin which are too thin to reduce the lumen appreciably. They may if laid down repeatedly on top of one another, give rise to considerable thickenings; but these do not encroach on the lumen to any extent, because such thickenings, by reducing elasticity usually lead to dilatation, and this more than compensates for any encroachment. Thus the arteries of aged people are commonly dilated although many of the lesions in them are obviously thrombotic.

Narrowing is therefore by no means a constant feature of arterial thrombosis; but nevertheless when present it is a fairly sure sign of that process, and, since it is only when there is narrowing that atherosclerosis is likely to be dangerous, it follows that thrombosis is the one factor of importance in fatal coronary disease. When we consider all the possible ways in which thrombosis may be influenced by diet we shall cover a large part of this very involved problem.

Fig. 4—Ascending aortas from two rabbits illustrating the dilatation which results from cholesterol loading. (Frozen sections: Sudan IV and hæmalum. $\times 6$.)

(a) Aorta from rabbit weighing 2800 g. which was on cholesterol treatment for 7 weeks. One small deposit of foam cells is seen at (x) the vessel being otherwise normal. Almost the whole wall consists of medial coat, the intima comprising no more than a single layer of endothelial cells.

(b) Aorta from rabbit weighing 2200 g. after 9½ months' cholesterol treatment. Most of the wall consists of thickened intima; the media, which is greatly stretched, is represented by the thin dark line (m) at the periphery. (It should be explained that the contrast in diameter is probably somewhat accentuated by post-mortem contraction in the more normal vessel, the thickened vessel being fixed in the position of maximum dilatation by the almost rigid intima.)

* It should be explained that the term elasticity as applied to arteries does not refer to the so-called elastic tissue in their walls but to the resilience of the walls as a whole.

Thrombosis and Diet

There are two ways in which diet may conceivably play a part in arterial thrombosis. Firstly it may, by affecting the coagulability of the blood, increase the tendency to clotting; and secondly, by causing fatty changes in the arteries, it may promote mural thrombosis.

The first possibility has recently been suggested by Fullerton, Davie, and Anastasopoulos (1953) who showed that the alimentary lipæmia which follows fatty meals is accompanied by an accelerated clotting-time in vitro. The same was also found by Waldron, Beidelman, and Duncan (1951). As Fullerton and his co-workers point out, a factor of lipid nature is concerned in blood coagulation, and an excessive intake of fat may perhaps increase it. It is well however to recall that there is also a lipid-inhibiting factor in coagulation; and the probabilities may thus cancel out. We do not yet know whether an accelerated clotting-time in vitro actually signifies an increased tendency to thrombosis, and any hypothesis of this kind is difficult to put to the test; but we may justifiably take the evidence of cholesterol experiments, since it is on them that the diet hypothesis mainly rests; and, as it happens, they provide no confirmation. In none of the rabbits were arterial thrombi to be found, in spite of the fact that cholesterol—the substance most frequently cited as the dangerous food constituent—was greatly in excess in the blood. We can only await further information on this point, especially with regard to the phenomenon of coagulation in other species.

The second possibility—that diet may lead to mural thrombosis by damaging the arterial walls—is of course the root of the diet hypothesis. Fatty lesions have long been regarded as the cause of mural thrombosis, and Rannie and I undertook the feeding experiments in the hope that we might demonstrate thrombi in relation to the cholesterol lesions and so bring these into line with coronary disease. But in this we were disappointed. Despite extreme disorganisation of the vessels, there were never any fibrin formations, and we were forced to conclude that neither an excess of cholesterol nor the consequent arterial lesions were in themselves sufficient to promote thrombosis in rabbits.

Nevertheless there can be little doubt that in man arterial lesions play a part in the development of mural thrombosis, for we almost never find such thrombi without some underlying fatty change. Some of the fatty changes are themselves secondary products of thrombi; but others are almost certainly of a primary nature, and, if not dependent on diet, are at least related to some disturbance of the fat metabolism. Superficial fatty streaking of the aorta is probably in this category, and it is not infrequently attended by fine fibrinous encrustations on the aortic surface (Duguid 1948). It can hardly be put down to diet, since it is mostly found in young subjects who have died from acute febrile conditions in which an excessive intake of rich foods is unlikely; but as I have said, lesions of a very similar kind can be seen in older subjects and some of them may be of dietary origin. We know that old people tend to have abnormal lipids circulating in their blood after heavy meals, and they may perhaps get into the arteries and lead to thrombosis. Such is of course the conception on which the diet hypothesis is based, and it is one that cannot be entirely discounted; but it leaves out of consideration one point of paramount importance with regard to vascular thrombosis, and that is its inherent variability.

Factors Governing Arterial Thrombosis

We have seen that the cholesterol lesions do not lead to thrombosis in rabbits, and this is quite in keeping with what we frequently find in man. Few observers can have failed to be impressed with the fact that there

may be widespread atherosclerosis of the aorta and other vessels, even with ulceration, and yet little or no thrombosis. We have been given to understand that the rapidity of the blood-stream in the larger arteries limits fibrin formation, and this is perhaps to some extent true; but when on occasion we find quite large mural thrombi in these same vessels, in people who have been active up to the time of death, speed of blood-flow does not seem to be the whole explanation.

To anyone who tries to produce arterial thrombosis in animals by injuring the arteries it becomes evident that there are refractory states, in which thrombi will not readily form, even with severe damage, and irrespective of the speed of the blood-flow. There are also states in which thrombi, having formed, rapidly disappear; and it would seem that there are factors in the blood—possibly anticoagulant substances, or possibly fibrinolysins as suggested by Mole (1948)—which in favourable circumstances control fibrin formation, and so make arterial lesions potentially less dangerous.

On the other hand there are the converse states, which may be described as thrombophilic. In cases of sudden death from coronary thrombosis I have several times noticed that the thrombotic process was not confined to the site of occlusion in the one coronary artery, but was widespread and prominent in the aorta and other vessels. This suggests that, when the fatal occlusion occurred, some thrombogenic influence, more powerful and generalised than mere local damage to the vessel walls, was at work; and this I believe is the factor we must aim at controlling if we are to reduce the incidence of coronary disease.

Undoubtedly intimal lesions are a contributing factor in mural thrombosis; but they are not the controlling factors, for there is no consistent correlation between the severity of the lesions and the size of the thrombi. Sometimes quite large masses of fibrin are formed on lesions which seem comparatively insignificant, and vice versa. It is obviously not the underlying lesion but some factor in the blood that determines how large the thrombus shall be, and that is what counts in so far as vascular impairment is concerned.

The Danger of Fatty Lesions

In the past we have looked on coronary thrombosis as a complication of atherosclerosis, but we must now regard it as a factor in this condition. Where there is much narrowing of an artery there is usually evidence of recurring mural thrombosis; and, while we may suspect that the process arises in the first place on some primary fatty lesion, its subsequent progress is simply a succession of one mural thrombus leading to another. Thus if a primary fatty change comes into the picture, it may be only at the initial stage, and long before the disease has begun to assume dangerous proportions.

With these considerations in mind one is less inclined to attach much importance to the presence of fatty changes. As Geiringer (1950) and others have shown, such changes are an almost constant feature of the aorta from childhood onwards, and we know that they are compatible with long life. They may, it is true, provide the foci in which thrombi develop, when conditions are set for thrombosis; but their severity seems to be a matter of minor importance. Fatal thrombosis is more likely to occur in a coronary artery which is narrowed by a dense fibrous thickening as in (fig. 2) than in one which is very fatty.

The Basis of the Diet Hypothesis

The idea that atherosclerosis is connected with diet arose out of an impression that fatty changes in arteries were prevalent in diabetics, gouty persons, alcoholics, and fat people who had presumably lived well; but we now know that some of the fats which appear in athero-

sclerosis are products of thrombi and are therefore secondary. Since they are probably derived from the lipids present in the blood when the thrombi are formed, it is not surprising that they should be prominent in diabetics and others who are prone to lipæmia. They may in fact be related to diet and yet have nothing to do with the cause of atherosclerosis.

In more recent years the mainstay of the diet hypothesis has been the cholesterol experiments. The fact that arterial lesions can be produced by giving an excess of a normal metabolite seems to put the hypothesis on an unassailable footing until we examine it critically. When we do so we merely find that to produce the lesions far more cholesterol is needed than is ever likely to be derived from a normal human diet, and that when produced these lesions are not of the kind which leads to vascular insufficiency.

The hypothesis therefore rests on slender foundations, and we have, I think, allowed ourselves to be too much influenced by it in our approach to the problem of coronary disease. Certainly much valuable information about the metabolism of fats has been collected, but before we can apply it to coronary disease we must be clear in our minds as to what we mean by that term. If we simply mean fatty changes in the coronary arteries, then we refer to a condition which is almost universal in adults. It may perhaps be related to diet, although there is no clear evidence on that point, but it is not the condition responsible for cardiac impairment and sudden death.

This problem will remain confused until it is more generally recognised that there are two different forms of atherosclerosis involving different pathological processes. They may present similar histological pictures, and they are often indistinguishable, but they are vastly different in their causes and effects. The form with which we are mainly concerned is the one which leads to coronary occlusion, and we know that in this form thrombosis is the important factor. It is possible that diet may have some effect on thrombosis, since nutrition must be a factor in most biological processes; but, when there are so many other important factors to be considered, there is a danger in allowing ourselves to be led too far along this line of approach by what may be a misleading hypothesis.

"I should like to suggest that intelligent behaviour may admit of differences in kind as well as in degree. For me, intelligent activity consists in grasping the essentials in a given situation and responding appropriately to them. This can scarcely claim to be a definition and it is certainly not precise. I prefer 'intelligent activity' to 'intelligence' because I wish to avoid the suggestion of some one trait which an individual simply possesses, to a greater or lesser extent. I use the word 'activity' in its widest sense, not necessarily implying activity which is overt at the time."—A. W. HEIM, *The Appraisal of Intelligence*, London, 1954, p. 29.

AUGMENTED RESPIRATION AN EMERGENCY POSITIVE-PRESSURE PATIENT-CYCLED RESPIRATOR

IAN DONALD

M.B.E., M.D. Lond., B.A. Cape Town, M.R.C.O.G.
 READER, INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY,
 UNIVERSITY OF LONDON

The principle of augmented respiration—in which spontaneous respiratory effort is amplified—has already been discussed, and the servo respirator used for the purpose has been described (Donald and Lord 1953). Experience has shown, however, that in treating respiratory difficulties in the newborn there is also need for an emergency type of apparatus which can be brought into action more rapidly. The servo respirator is not always readily available, and the staff who can handle it have to be mustered. Moreover, in spite of our efforts to forecast the likely course of events, with the help of radiography (Donald and Steiner 1953) and spirometry, delays often arise from the difficulty of deciding whether the baby really needs to be put in the servo respirator. When signs of respiratory distress develop—usually soon after delivery—it is far from easy to say whether spontaneous recovery is likely to take place; and in some cases a series of cyanotic attacks may be the first warning of trouble.

Of the 28 infants so far treated with the servo respirator, those whose treatment began before the age of three hours have done much better than those treated later.

In table I asphyxial deaths include cases of atelectasis (with and without hyaline membrane formation), and cases of intraventricular hæmorrhage, which is nearly always the result of asphyxia (Claireaux 1953b), and then operates as a secondary cause of further asphyxia. In 7 cases the infants were non-viable, being of less than twenty-eight weeks' gestation; and, since there was no question of their maintaining respiration, treatment was started without delay. Hence they all appear in the group in which treatment was started before the age of three hours. In this group 1 viable child died of hyaline membrane, and in this instance the respirator had failed mechanically.

To cover delays in preparing the servo respirator or to meet respiratory emergencies we clearly needed a respirator which could be operated at once via a mask, with the child still in its cot or incubator.

Our routine treatment of a cyanotic attack consists in pharyngeal, œsophageal, and gastric aspiration, with administration of gastric oxygen; but, if the child does not quickly revive, a respirator is used. Intubation of premature or very sick neonates is not well tolerated, and, without intubation, positive pressures applied to the face without regard to the timing of the child's respiratory efforts tend simply to drive air or oxygen down the œsophagus into the stomach. If on the other hand, a positive pressure is applied synchronously with contraction of the diaphragm in inspiration, it closes the

Figures in parentheses indicate previable fetuses of less than 28 weeks' gestation.

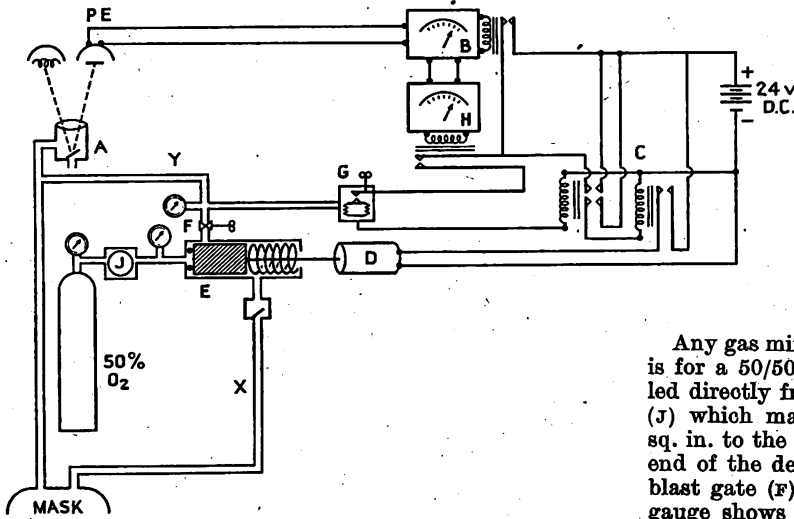

Fig. 1—The electrical circuit.

lower end of the oesophagus and allows the gases to take their intended route to the lungs—which alone are likely to achieve rapid oxygenation of the blood. The principle of augmented respiration therefore applies.

The Apparatus

For short-term emergency treatment we now use a positive-pressure patient-cycled respirator—known locally as “the puffer.”

As in the servo respirator, the triggering of intermittent pressures is achieved by a photo-electric mechanism, in which the flap of the inspiratory valve consists of a mirror (A) (figs. 1 and 2) whose slightest movement deflects a light-beam from a photo-electric cell (P.E.). The beginning of an inspiratory effort thus causes a change in voltage output from the cell. This is amplified (B) to operate the electromagnetic relay system (C) which controls the solenoid (D). The solenoid moves the piston valve (E), which not only closes off the exhaust pipe (X) from the face-mask but opens the delivery pipe (Y) through which a suitable gas mixture is fed under direct pressure to the face-mask. A blast gate (F) adjusts the rate of flow of gas. By means of an aneroid switch (G), which interrupts the circuit, pressures are prevented from exceeding a pre-set maximum.

The amplifier (B) includes the refinement of a “paralysis time” circuit which introduces a refractory phase and allows the amplifier to pass on only the first impulse from the photo-electric cell and to reject all others over a pre-set period—usually about a second. This prevents false and repetitive triggering.

A “hold-in” time circuit (H), in this case an ‘Elcontrol Weld Timer’ switch, is also necessary to keep the solenoid in action for a predetermined period after each triggering—in case sufficient pressure is not built up to operate the aneroid switch (G). H and G are connected in series so that the circuit shall be interrupted by the aneroid pressure cut-out switch or by the hold-in timer, whichever operates first. In other words, if the maximum permitted pressure is achieved before the hold-in time has expired, the solenoid will be inactivated, the spring behind the piston valve will shut off the supply of compressed gas mixture, and the expiratory pipe will be opened; but if (perhaps

because the mask does not fit) the pre-set pressures are not achieved within the hold-in period, the time switch will first interrupt the supply of gas. This prevents the solenoid from holding the piston valve in the open position which would otherwise continue indefinitely and waste the gas mixture.

The hold-in time and the paralysis time must not be allowed to overlap, and the former must be adjusted not to equal or exceed the latter.

Thus at the completion of each cycle, the apparatus is ready to respond to the next triggering from the inspiratory valve.

Any gas mixture can be supplied. Our usual preference is for a 50/50 mixture of oxygen and nitrogen, which is led directly from a cylinder to a pressure-reducing valve (J) which maintains a delivery pressure of 1.8 lb. per sq. in. to the piston valve. The pressure at the proximal end of the delivery pipe to the mask is adjusted by the blast gate (F) to about 30 cm. of water. A manometer gauge shows the pressures achieved in the mask itself, and these are usually about 15 cm. of water, though different pressures can be achieved at will. The mask is simply a soft rubber U.S. Army resuscitation mask applied *upside down* so that the baby’s chin fits into the apex which would normally lie over the bridge of an adult’s nose. The base of the mask lies over the baby’s forehead, and with a very little practice almost any size or shape of face can be satisfactorily fitted. The mask can be lightly held in place by spreading the fingers round the sides.

The aneroid switch controlling the maximum permitted pressure, and the “hold-in” and “paralysis” times seldom require adjustment, and all that is necessary in a given emergency is to switch on the apparatus, turn on the gas supply, and (having aspirated the pharynx) apply the mask to the face—the whole operation taking no more than a minute.

Fig. 3 (case U.C.)—Tracings obtained with Smyth anemometer. (a) Spontaneous respiration amplified at A with puffer. (b) AA = non-triggered amplification. AB = patient-triggered amplification.

If the baby has stopped breathing altogether, and for the moment there is no respiration to amplify, an occasional pinch and release of the delivery tube (γ) is sufficient to trigger off a surge of positive pressure to the mask. This has none of the advantages of augmenting respiration; but when the baby does take a breath, even though small, that breath will instantly be increased.

Fig. 3 shows that much greater ventilation is achieved when spontaneous respiration is amplified than when gases are supplied under pressure without regard to the child's own respiratory efforts. This tracing was made at University College Hospital by Dr. Norman Smyth who applied his nasal anemometer apparatus underneath my mask. It gives an indication of the rate of flow of gas through the nostrils.

Application in the Adult*

Although the apparatus was originally intended for babies, my colleagues in the department of medicine of the Postgraduate Medical School, Dr. Russell Fraser and Dr. Charles Fletcher, encouraged me to adapt it for adult use. This was done quite simply by fitting alternative large-bore delivery pipes. It was not long before an opportunity arose for treating an adult, and I am indebted to Prof. Ian Aird for permission to describe the following case.

The patient, a woman aged 62, had a straightforward cholecystectomy. A curare derivative was used to obtain relaxation, and after the operation, which lasted just over an hour, spontaneous respiration did not return, despite intravenous injection of nikethamide, atropine, and neostigmine. For more than five hours artificial respiration was continued by rhythmic squeezing of the bag of the anaesthetic machine, and during this time a total of 8.5 mg. neostigmine methyl sulphate and atropine gr. $\frac{1}{12}$ was given. After three and a half hours feeble spontaneous respiration began, but it was inadequate without continued assistance and a cabinet respirator was sent for.

About five and a half hours after the operation, while the arrival of the cabinet respirator was awaited, the puffer was applied, the patient's spontaneous respiratory efforts being sufficient to operate the sensitive trigger mechanism. Her colour at this time was somewhat grey. After five minutes' treatment with the apparatus an adequate depth of respiration was achieved, and this was maintained thereafter spontaneously. The corneal reflex returned and half an hour later she was returned to the ward showing signs of regaining consciousness. The systolic blood-pressure now dropped precipitately to 60 mm. Hg, but her general condition responded to routine resuscitative measures. Convalescence was complicated by a small pulmonary embolus after the first postoperative week, but was then straightforward.

In this case the use of the apparatus was immediately followed by return of adequate spontaneous respiration.

The patient was not intubated at the time, and if, as I think probable, she was suffering from prolonged pulmonary underventilation, with accumulation of carbon dioxide, her recovery may well have been due to removal of this carbon dioxide with the help of the apparatus.

Results in the Treatment of Neonates

Up to the end of 1953, 25 cases had been treated with the puffer. Of these, 4 were also (and mainly) treated with the servo respirator and therefore appear in table I. The remaining 21 cases are analysed in table II.

It is our practice to keep the puffer standing by, adjusted and ready for immediate action in cases of severe prematurity or where attacks of respiratory failure threaten. Certain members of the nursing staff in the Premature Baby Unit at Hammersmith Hospital are now capable of handling the apparatus well and have repeatedly been able to restore satisfactory respiration and oxygenation before medical help arrived.

It must here be repeated that the apparatus is not used without first thoroughly aspirating mucus from the pharynx.

NON-SURVIVING CASES

Intraventricular hæmorrhage was the predominant cause of death in 4 of the 14 non-surviving cases and hyaline membrane was also present in 2 of them. One had a tear of the tentorium. Except in one of the cases demonstrating hyaline membrane in marked degree, all lobes of the lungs floated at necropsy. In 3 of the above cases the period of gestation was less than twenty-eight weeks and the infant was therefore not viable.

Atelectasis with hyaline membrane was responsible for death in a further 5 cases, in 2 of which intraventricular hæmorrhage was also a contributory factor. In a 6th case hyaline membrane was present but the primary cause of death was intrapulmonary hæmorrhage.

The following case is worth quoting because a mild degree of pulmonary damage was sustained.

TABLE II—RESULTS WITH PUFFER ALONE (21 CASES)

Weight (lb.)	Lived	Hyaline membrane	Intra-ventricular hæmorrhage	Hyaline membrane and intra-ventricular hæmorrhage	"Asphyxia" unspecified	Intra-pulmonary hæmorrhage
-2	0	0	(1)	(1)	0	0
2-3	3	1	0	(1)	0	1
3-4	1	1	1	1	1	0
4-5	2	1	0	1	0	1

Total	9	3	1+(1)	2+(2)	1	2

Figures in parentheses indicate pre-viable fetuses of less than 28 weeks' gestation.

* A fair copy of my prototype apparatus is now being developed by British Oxygen Company Ltd.

Case Lo2.—The second of twins; breech delivery at thirty weeks' gestation; birth-weight 2 lb. 10 oz. At birth lively and pink, but signs of inspiratory recession of the chest wall developed within half an hour. Radiographs taken at one hour, six and a half hours, and eighteen hours showed the evolution of signs which we have come to associate with the development of hyaline membrane. The child was treated repeatedly with the puffer and then transferred to the servo respirator from which it was removed at the age of thirteen and a half hours because its condition then seemed satisfactory. One hour later, however, its condition was again very poor. It was repeatedly aspirated, and revived with the puffer.

After replacement in the servo respirator, the child appeared to progress fairly well throughout the day until one of the valves in the apparatus jammed. The puffer was now connected with the head chamber in order to supply positive-pressure assistance. Meanwhile the faulty valve was repaired.

All went well thereafter until the age of twenty-four hours when a series of cyanotic attacks recurred. At twenty-five hours the child was again breathing very well without augmentation. During the next four hours the colour gradually deteriorated but the respirator was not switched on again because the breathing appeared to be fairly regular. At twenty-nine and a half hours the child died in a prolonged apnoeic attack which both machines operating simultaneously failed to modify.

At necropsy there was severe emphysema of the left lung. Four large bullae were present in the posterior medial margin of the left upper lobe and there were numerous smaller emphysematous bullae throughout this lobe. The use of servo respirator and puffer simultaneously may have been responsible for the emphysema. Dr. Claireaux, who performed the necropsy, did not regard the emphysema as the cause of death and he reported extensive hyaline membrane. There was no pneumonia.

There were 3 cases in which the cause of death could not be definitely determined other than as "asphyxia." One of these infants weighed only 1 lb. 6 $\frac{3}{4}$ oz. and, having been treated in the servo respirator as well, is included in table I. Pulmonary aeration was no more than moderate in all of them, but all lobes of the lungs floated at necropsy. The usual picture histologically was that of areas of atelectasis alternating with areas of over-distension.

SURVIVING CASES

Of the 11 infants who survived, 2 were also treated in the servo respirator and therefore appear in table I instead of in table II. The largest weighed 5 lb. 8 $\frac{1}{2}$ oz. and the smallest 2 lb. 6 oz. The indications for treatment were the appearance of severe and increasing inspiratory recession of the thoracic wall, the development of apnoeic and cyanotic attacks, or very shallow and infrequent breathing associated with clinical signs of cyanosis. As these babies survived it is impossible to discuss the underlying pathology treated.

Case Na, weighing 2 lb. 6 oz., was delivered in a nursing-home at thirty weeks' gestation and was admitted aged eighty minutes. The condition deteriorated at three and a half hours and multiple cyanotic attacks necessitated the use of the puffer intermittently at each attack during the first three days of life. Radiographs showed fine miliary stippling of the lungs which became more conspicuous and coarser by ten hours but cleared by sixty hours. At the age of twenty-three days the child developed pneumonia but recovered and has since done well.

Case Va was delivered spontaneously face to pubis at thirty-nine weeks' gestation and weighed 4 lb. 15 oz. The condition at birth was one of shock and the child was intubated. Positive pressures were applied endotracheally by the usual routine method for sixty minutes without spontaneous respiration becoming established. The puffer was then used and the child quickly recovered and did well thereafter. Possibly a very lucky coincidence.

Case Oa.—Breech delivery at thirty-two weeks; birth-weight 3 lb. 5 oz. Inspiratory recession and grunting respiration were soon apparent. The puffer was used repeatedly during the first six hours of life, during which time trip

spirometry showed considerable improvement from 420 ml. to over 700 ml. per min. The child thereafter did well.

Case Lo1 was the first of twins born precipitately at thirty weeks' gestation. Birth-weight 2 lb. 7 oz. Pethidine had recently been given to the mother. The child was apnoeic and obviously narcotised, and nalorphine ('Lethidrone') 0.5 mg. was given into the cord. This revived the child, but its colour remained blue and there was considerable inspiratory recession. The puffer was then used and its colour improved at once. Progress thereafter was uninterrupted.

Nalorphine greatly contributed to the successful outcome here. In the following case it was given belatedly.

Case Go.—Birth-weight 2 lb. 12 oz. Rapid delivery three and a half hours after morphine had been given to the mother because of mixed accidental antepartum haemorrhage. At birth the child was flaccid and grey and took only occasional gasps. Gastric oxygen had no apparent effect. The puffer was thereupon used—without much immediate benefit, for the respirations were infrequent. Nikethamide 0.25 ml. was injected intravenously, with transient benefit, and treatment with the puffer was continued. At sixty minutes nalorphine (0.5 mg.) was injected, and regular but slow respiration was established at once. Treatment with the puffer was continued for another half-hour but the colour did not become really satisfactory until a high oxygen concentration was given by the apparatus.

In this case the Coombs test was strongly positive, and after a replacement transfusion the child did well. The nalorphine should have been given earlier.

Case Ee.—Normal delivery at thirty-seven weeks' gestation. Birth-weight 5 lb. 2 oz. This child did not appear to be breathing satisfactorily and at one hour fifty minutes the minute volume was only 330 ml. Fifteen minutes' continuous treatment was given with the puffer at the age of two and three-quarters hours. I was not present personally but my colleagues noted improvement clinically, and at four hours thirty-five minutes the minute volume was 550 ml. Progress thereafter was uneventful.

Case Bo.—Spontaneous premature delivery at thirty-one and a half weeks following premature rupture of the membranes for the preceding two and a half weeks. Birth-weight 4 lb. 2 $\frac{1}{2}$ oz. The child cried at birth but severe recession developed within four minutes. The colour was poor and treatment with the puffer was given intermittently with benefit. The signs of inspiratory recession gradually disappeared within a few hours.

The apparatus was here used intermittently to correct evident asphyxia. It is unlikely that it directly influenced the disappearance of the recession.

Case U.C.—Rapid delivery at term with foetal distress in the second stage. Birth-weight 5 lb. 8 $\frac{1}{2}$ oz. The child refused to take more than occasional gasps and its colour remained very poor.

Delivery had taken place at another hospital and I was asked to see the case because there were no signs of spontaneous improvement during three hours. I took the puffer with me, and treatment was started at approximately the age of four hours and maintained by my enthusiastic colleagues at this hospital for nearly three hours in spite of my gloomy forecasts. It seemed certain that the child had an intracranial haemorrhage and I doubted whether it was worth persisting. Dr. Norman Smyth, however, applied his anemometer under the face-mask, and fig. 3 is a sample of the tracings obtained. Ventilation appears to have been increased. The child slowly recovered and is now eleven months old and progressing normally.

Case Ar.—District delivery at approximately thirty-four weeks. Birth-weight 3 lb. It cried well at birth. On admission at three hours, the temperature was 95°F. Cyanotic attacks repeatedly occurred and intracranial bleeding was provisionally diagnosed. Nevertheless the puffer was used repeatedly to restore oxygenation and after the age of twenty-four hours no further cyanotic attacks occurred. Apart from subsequent difficulty with feeding the child has since done well.

The salvage of babies suffering from intracranial bleeding might be regarded by some as questionable;

but, since the diagnosis cannot be made with certainty before death, it is worth giving the child the benefit of the doubt, as these last two cases indicate.

Summary and Conclusions

Further experiences in augmented respiration showed the need for an emergency type of respirator as an ancillary to the main servo respirator.

A positive-pressure patient-cycled respirator, operated via a face-mask, is described and the results of its use are briefly reported.

The recovery of the surviving infants cannot necessarily be attributed wholly to the use of the respirator; but our observations have at least shown that, at the pressures normally employed, the treatment is harmless and temporarily beneficial. Its object is no more than to combat asphyxia for the time being and so allow the child time in which to achieve normal respiration if it is capable of doing so.

Grateful acknowledgments are made to the staff of the Premature Baby Unit, Hammersmith Hospital, for their coöperation, and to the technical staff of the Department of Biophysics of the Postgraduate Medical School of London. This research has been made possible by a Leverhulme scholarship awarded for the purpose by the Royal College of Obstetricians and Gynæcologists.

HYPOCHROMIC ANÆMIA IN R.A.F. RECRUITS

B. J. LEONARD
 M.D. Manc.

SQUADRON-LEADER, R.A.F.

From the Royal Air Force Hospital, West Kirby, Cheshire

IDIOPATHIC hypochromic anæmia in the male has been regarded as rare.

Wintrobe (1951) suggested that, if hypochromic anæmia was found in a man it was almost always caused by occult loss of blood, unless there had been a gastric operation.

Whitby and Britton (1950) describe the condition as exceedingly rare in males. Faber (1913), who first drew attention to this disease, reported 3 cases in males out of 20 cases; Davies (1931a) 4 cases in males out of 55 cases, and Witts (1930) 1 case; and Britton (1936) found 4 cases in males out of 66 cases.

Witts and Burgher (1934) published 26 cases in males, of whom 8 were aged less than thirty; they noted a tendency to immaturity in the lower age-group. Filo (1933) described eunuchoidism or underdevelopment of the genitalia with this type of anæmia in young males. Thomson (1943) found 9 cases of hypochromic anæmia in adolescent males, of whom 4 had splenomegaly.

Shorthouse and King (1951), who described 20 cases of hypochromic anæmia in army recruits, also discovered a tendency to immaturity and noted that the symptoms did not appear until after a few months' service.

This paper deals with 50 cases of hypochromic anæmia detected by routine blood examination of young men on entry into the Royal Air Force, which have been investigated and treated at this hospital. As all these men had recently undergone medical examinations to assess their fitness for military service and had all been passed grade 1, there is evidently some clinical difficulty in detecting the condition. The investigations were designed to attempt to answer the following questions:

- (1) What is the incidence of anæmia in R.A.F. recruits?
- (2) What types of anæmia are we dealing with?
- (3) What are the social background, symptoms, and clinical signs of anæmia in the young male?
- (4) How should these cases be treated?

Methods

Hæmoglobin values (oxyhæmoglobin method) were estimated in 1000 recruits in their first week of training. After this all of 3221 recruits entering the camp were screened by the copper-sulphate method. The total number of recruits examined was therefore 4221. Among these, 50 were found to be undoubtedly anæmic (Hb 12 g. or less per 100 ml.) and were admitted to a special ward for investigation and treatment.

The following determinations were made on 5 ml. of venous blood: (1) hæmoglobin (Medical Research Council grey-wedge photometer); (2) packed-cell volume; (3) red-cell count; (4) absolute values; (5) total and differential white-cell count; (6) reticulocyte-count; (7) erythrocyte-sedimentation rate (E.S.R.); and (8) blood fragility.

The following tests were also done as a routine: (1) fractional test-meal (combined alcohol and histamine method); (2) benzidine test (occult blood was tested for on three consecutive daily samples of faeces); (3) a mid-stream specimen of urine was examined for albumin, sugar, and deposit; (4) radiography of the chest; (5) total faecal fat (in many cases a four-day fat-balance test was made); and (6) examination of bone-marrow.

In the presence of gastric hyperacidity and a history suggesting peptic ulceration, or, if occult bleeding was detected, the whole of the gastro-intestinal tract was radiographed.

Findings

Of these 50 men with hypochromic anæmia 2 had bleeding from the gastro-intestinal tract and 1 acholuric jaundice. In the remaining 47 no cause of the anæmia was detected, and the condition must be regarded as idiopathic (table 1).

TABLE I—BLOOD FINDINGS

* 100% = 14.8 g. per 100 ml.

THE PATIENTS

Incidence.—In 36 (0.9%) of 4221 R.A.F. recruits aged from eighteen to twenty the hæmoglobin was less than 10.4 g. per 100 ml., and in the remaining 11 (0.2%) it was 10.4–12.0 g. per 100 ml. (table 1).

Social Background.—The occupations of the recruits before enlistment did not appear to be significant, but this might well be expected in youths aged eighteen. The social classification of their fathers is a more reliable indication of their background :

Fathers' occupations	No. of patients
Unskilled	24
Semi-skilled	8
Skilled	2
Unemployed	7
Fathers dead	6

It can be seen that in most cases the fathers followed unskilled occupations and would come under social class iv or v of the Registrar-General's classification of the population. The number of fathers who, through either ill health or death, were not wage-earners, was high—13 out of 47.

Size of Family Unit.—The average number of siblings for each patient was three.

Geographical Distribution.—Most of the patients came from the North and Midlands, but the significance of this cannot be assessed without figures for the whole of the R.A.F.

SYMPTOMS AND SIGNS

Most of the patients had no symptoms at all, and only 1 had visited his family doctor because of symptoms caused by anæmia. 9 (19%) complained of breathlessness and tiredness of a very mild degree. Dyspepsia and diarrhoea were not complained of, even by those with achlorhydria. A family history of anæmia was reported by 2 patients, but without examining the blood of their parents and relatives this figure might be very misleading.

Their appetites were very good—a fact verified on the ward at mealtimes. Only 4 disliked meat and green vegetables or other iron-containing foods.

The unreliability of pallor of the skin as a sign of anæmia was confirmed, 34 out of 47 having no such pallor. Pallor of the conjunctivæ, gums, and nail beds were almost constant features. Flattening of the nails was seen in 11 (23%), but only 1 had definite koilonychia. The spleen was palpably enlarged in 2 but became impalpable after treatment. Most of the patients appeared dull and lifeless, and their facial expressions depicted easy fatigability. They were of all heights from 5 ft. 2 in. to 6 ft. 5 in. and most of them were built proportionately to their height; none showed signs of loss of weight. As a group they did not show immaturity or underdevelopment of the genitalia.

The 1 man (case 2, with Hb 6.6 g. per 100 ml.) who had significant symptoms before enlistment was a farm labourer aged eighteen and 6 ft. 3 in. tall who had been dismissed by his employer for not pulling his weight. On two occasions he had had severe dyspnœa while doing farm work. Treatment with an iron tonic had improved the dyspnœa on both occasions. Each attack of dyspnœa coincided with the threshing season, when an extra physical effort was required of him; during the rest of the year he had carried on with his farm work without symptoms. This case demonstrates how symptoms due to anæmia must be assessed according to physical effort required by the patient's occupation and other activities.

BLOOD FINDINGS

The low mean corpuscular hæmoglobin concentration (M.C.H.C.) confirmed a state of iron deficiency, and some recruits were severely anæmic (table 1). Wintrobe (1951) regards a M.C.H.C. of 22% or less as indicating extremely severe anæmia. In 10 patients the M.C.H.C. was 22% or less. Microcytosis was not found to be a prominent

feature, and the red-cell count was normal in most cases. Microcytosis and a low red-cell count may well be features of a long-standing case.

The appearance of the red cells invariably showed variation in staining, shape, and size. The more severe the anæmia the more pronounced were these findings and the greater was the percentage of cells affected. Elliptical red cells, seen in several films, disappeared after treatment and thus excluded elliptocytosis. Scanty stippling of the red cells was seen in a few blood films, but nucleated red cells were not seen. The presence of target cells and moderate anisocytosis with hypochromic anæmia seems to be a good indication to look for steatorrhœa (Cooke et al. 1948); several such cases have been seen in this laboratory.

The total white-cell count was normal, and there was no considerable granulocytopenia. The reticulocyte count in most of the cases was significantly less than 1%, and in none did it exceed this figure. The platelets appeared normal in number, shape, and size. The E.S.R. and red-cell fragility were always normal.

BONE-MARROW FINDINGS

No published work on the marrow picture in this type of anæmia in young males could be found. Bone-marrow examinations were made in 37 patients. The method of taking the marrow, the staining, assessment, and terminology were those described by Israëls (1948).

The marrow was hyperplastic in 31 and normal in the remaining 6. Usually the lower the hæmoglobin, the more hyperplastic was the marrow. The hyperplasia involved all forms of the normoblastic series. The normoblasts were smaller than normal and the cytoplasm reduced in quantity and basophilic in tint. Table II shows that the range found for the various types of normoblasts included a higher upper limit in all forms.

Hæmocyto blasts did not share in the hyperplasia in any marrow examined. In many films the increase was mainly in the pro-erythroblasts and early basophilic normoblasts. Megaloblasts were not seen in any film. The nuclei of many of the early basophilic erythroblasts were not absolutely typical of any stage in the normoblast series, but a megaloblastic nuclear pattern was certainly not present. Whether these cells could be classified as transitional megaloblasts is open to question (Innes 1949, Israëls 1951). Giant metamyelocytes were not seen in any film, and primitive white cells were not found to be increased in number.

In the hæmoglobin range of 4.9–9.0 g. per 100 ml. the average myeloid/erythroid ratio was 1.9/1.0. In the higher hæmoglobin range of 9.1–10.8 g. per 100 ml. the average ratio was 2.5/1.0. Usually the lower the hæmoglobin, the more closely the myeloid/erythroid ratio approached unity. A ratio of 1/1 or less was never found, even in the severest anæmia.

The bone-marrow findings concur with Leitner's (1949) statement that only a moderate degree of normoblastic hyperplasia is usually found in iron-deficiency anæmia. Whitby and Britton's (1950) statement that normoblasts of various grades of maturity form 50% or more of the total nucleated-cell count was not confirmed in any case in this series.

TABLE II—NORMOBLAST SERIES

Forms	Normal range (%) (Israëls 1948)	Range found (%)	Average (%)
Pro-erythroblasts	0.5–4.0	0.5–5.0	3.6
Early normoblasts	1.0–5.0	2.0–11.0	5.6
Intermediate normoblasts..	12.0–20.0	4.0–25.0	15.4
Late normoblasts	6.0–10.0	4.0–12.0	7.0

TABLE III—RESULTS OF TEST-MEALS

	Achlorhy- dria (%)	Hista- mine- fast achlor- hydria (%)	Normal acidity (%)	Hypo- chlor- hydria (%)	Hyper- chlor- hydria (%)
Davidson and Fullerton's (1938) series in females ..	64.9	45.6	17.5	14.6	3.0
Present series ..	62	43	25		13

RELATION OF GASTRIC ACID TO ANÆMIA

Bennett and Ryle (1921), using the gruel test-meal, discovered 4 cases of achlorhydria (not histamine-fast) in 100 healthy medical students.

Lander and MacLagan (1934) found an incidence of 1% after the injection of histamine in a comparable series. Doig et al. (1950) found 1 case of histamine-fast achlorhydria in 134 students.

Fractional test-meals were given as a routine in the present series. 50 ml. of 7% alcohol was given, and 0.5 mg. of histamine was given if no free hydrochloric acid was found.

Table III shows the fractional test-meal findings in this series compared with Davidson and Fullerton's (1938) findings in middle-aged women, with idiopathic hypochromic anæmia. The incidence of achlorhydria and histamine-fast achlorhydria in the two series are virtually the same. In the present series hypochlorhydria was not separated from normal acidity; the dividing line is arbitrary, and the level of acid depends to some extent on whether alcohol or gruel is used. Davidson and Fullerton (1938) emphasised the importance of diet in the aetiology of achlorhydria.

In this series almost every patient had a good appetite, and most of them were taking a reasonable amount of meat, vegetables, and fruit. The findings of comparable incidences of achlorhydria in young men and middle-aged women suggests that the achlorhydria precedes the anæmia or else comes on early in the development of idiopathic hypochromic anæmia.

Davidson and Fullerton (1938) suggested that histamine-fast achlorhydria might not necessarily be permanent. Fractional test-meals were repeated in 13 of the present cases with histamine-fast achlorhydria, from six to ten weeks after the start of treatment, when the hæmoglobin had returned to normal. 6 cases showed free hydrochloric acid—3 without histamine and 3 only after the injection of histamine. These findings are contrary to the generally accepted view on the irreversible nature of histamine-fast achlorhydria, and are hard to explain on any other ground than that of improvement in the blood hæmoglobin, with consequent increase in oxygenation of the gastric mucosa.

Achlorhydria was present in 16 of 21 patients with Hb 9 g. or less per 100 ml., and in 13 of 26 patients with Hb more than 9.1 g. per 100 ml. Although the series is small, this suggests a relation between achlorhydria and the hæmoglobin level. Davies (1931b) studied the gastric contents in cases of anæmia with achlorhydria and found that gradually progressive stages of secretory failure may occur, and that a link between idiopathic hypochromic anæmia and pernicious anæmia, on the basis of failure in gastric secretion, might be postulated.

It is interesting to postulate that there may be two types of histamine-fast achlorhydria, which could be differentiated by histological examination of the gastric mucosa:

(1) *Congenital* (and perhaps familial).—The acid secretory cells either may not have developed in the fetus, or may be hypoplastic and unable to produce acid. If this type is

associated with iron-deficiency anæmia, treatment would not restore the secretion of acid.

(2) *Acquired*.—Some pathological process or processes may cause the oxyntic cells of the stomach to stop producing acid. The histological picture in the early stage might be quite different—i.e., no lack of development of the oxyntic cells. In this type early detection and efficient treatment may restore the secretion of acid. If, however, the anæmia is long-standing, as in typical idiopathic hypochromic anæmia of women, the prolonged anoxæmia might permanently damage the gastric mucosa, and treatment would not alleviate the histamine-fast achlorhydria.

Treatment

The cases reviewed here were all treated with intravenous iron ('Neo-ferrum,' Crookes) because oral iron therapy was slow and unreliable. Saccharated oxide of iron was given in a dosage of 50 mg. on the first day, 100 mg. on the second day, and 200 mg. daily thereafter until the total dosage prescribed had been given. The total dosage was calculated as 25 mg. for every 1% deficit of Hb, the aim being to increase the Hb to 15 g. per 100 ml. No extra iron was allowed for depleted stores. Slack and Wilkinson (1949) showed that, in chronic infections, more than 25 mg. per 1% deficit of hæmoglobin was required, and a full response to this amount therefore helps to rule out chronic infections. Similarly, in idiopathic steatorrhœa and anæmias due to vitamin deficiencies, 100% utilisation of the iron administered would not be expected, because many patients would require folic acid, or the vitamin in which they were deficient, to restore the blood picture to normal.

The average daily increase in hæmoglobin was 0.34 g. at ten days and 0.19 g. at four weeks. The utilisation of the preparation was 100%. In most cases a small reticulocyte peak developed between the sixth and the eighth days but never exceeded 4%. The height of the peak had no constant relationship to the initial hæmoglobin level or the initial red-cell count. A reticulocyte-count of 2-3% after it had been less than 1% for several days was taken to be a definite reticulocyte response. A temporary erythrocytosis (packed-cell volume more than 50%) was noted in nearly every case and accounted for the M.C.H.C. reaching normal limits long after the hæmoglobin. Untoward reactions were not observed in any patient. The technique of giving the iron was that described by Slack and Wilkinson (1949).

Although most of the patients had no symptoms, after treatment a sense of well-being, more energy, and a greater interest in life were admitted by almost every patient.

Conclusions and Summary

Idiopathic hypochromic anæmia is common in young males, and is the commonest form of anæmia in R.A.F. recruits. Of 50 cases of hypochromic anæmia found among 4221 recruits, 47 could be regarded as idiopathic.

Most of the 50 patients came from large working-class families.

Symptoms were rare, even with severe anæmia.

The incidence of histamine-fast achlorhydria in hypochromic anæmia in young men, is the same as in middle-aged women with this type of anæmia. The associated histamine-fast achlorhydria was reversible in 6 of 13 cases.

Early detection and treatment of the anæmia are important for the well-being of the gastric mucosa.

The bone-marrow findings showed that the typical picture is one of moderate normoblastic hyperplasia.

Treatment with intravenous iron was safe, efficient, and reliable.

After treatment nearly all the patients experienced a sense of well-being, more energy, and more interest in life than they had been accustomed to.

I am indebted to Dr. J. F. Wilkinson, director of the department of hæmatology, Manchester Royal Infirmary, for

his advice and encouragement throughout this work. Group-Captain W. Stamm, principal specialist in pathology and tropical medicine, Royal Air Force, provided full facilities for this experiment. Air Commodore A. Rumball, consultant in medicine, Royal Air Force, gave every facility for the treatment of cases in the wards. I wish to thank the Princess Mary R.A.F. nursing sisters and laboratory technicians for their efficiency and co-operation in the many tests made in the wards and in the laboratory, and to the Director-General of Medical Services of the Royal Air Force for permission to publish.

SUDDEN suppression of urine is of such varied aetiology that few clinicians have not observed it and been required to treat it. A few cases may be caused by obstruction of the urinary tract, but most are the result of shock during which renal damage develops. If cortical necrosis is complete, the prognosis is hopeless; but this must never be assumed, because, if the lesion is less extensive and the main damage is to the renal tubules, the outlook is quite good provided the appropriate treatment is started promptly and given with care and attention to detail.

Suppression of urine often develops when least expected and when treatment is very properly being directed towards the resuscitation of the shocked patient. Herein lies a danger. In his concern to restore and maintain an adequate circulation the doctor may miss by many valuable hours the early diagnosis of anuria and (of far greater importance) by over-enthusiastic intravenous therapy may so disrupt the patient's fluid and electrolyte balance as to prejudice ultimate recovery from the anuria. In such cases, and in some others deteriorating under treatment, complicated procedures—e.g., exchange transfusions (Dausset 1950), peritoneal dialysis (Frank et al. 1948), and the use of the artificial kidney (Kolff 1952)—

may be required; but, even so, conservative treatment by restriction of fluids and a high-calorie diet containing little or no protein will be required.

When anuria is diagnosed at its onset, conservative treatment should be all that is required to allow the kidneys to recover. This treatment, though properly called conservative, must not be thought of as meaning therapeutic inactivity; it is rational and demands attention to detail for which "doing nothing is the least suitable epithet imaginable" (Black and Stanbury 1948).

We describe here in detail the successful management of a case of prolonged anuria (complete for 11 days, partial for a further 10 days) following septic abortion treated in a gynaecological ward of a general hospital. We believe that the methods adopted can easily be used by others who may encounter a similar case. The feature of the treatment to which we draw particular attention was continuous infusion through a catheter in the inferior vena cava for 17 consecutive days.

Case-record

A 3-para married woman, aged 31, was admitted in the early hours of April 1, 1953. She had last menstruated 17 weeks previously, and just over 2 months later she tried to procure abortion by taking 60 or more "corrective capsules" over a period of days. Violent purgation and vomiting followed but not abortion. So she syringed herself with a soap solution on the night of March 31 and was admitted to hospital some hours later.

On admission her general condition and physique were good, her temperature was 99.4°F, pulse-rate 100, and blood-pressure 110/75 mm. Hg. Her tongue was moist and clean, and her heart and lungs showed no fault. The size of her uterus, which was tender, was compatible with a 17-week pregnancy; the cervix admitted a finger-tip, and there was some fresh blood on the examining finger. The initial diagnosis was threatened abortion.

Later the same morning, coincident with the expulsion of the gestation sac, there was much vaginal bleeding, which was soon controlled by the injection of ergometrine 0.5 mg. The systolic blood-pressure fell to 90 mm. Hg, but after a transfusion, given without reaction, of one pint of whole citrated blood it rose again.

At operation at 12.45 P.M. the same day the cervix was found to be widely open, permitting the digital removal of several portions of offensive placental tissue. No curette was used, and bleeding was slight. At the operation a small quantity of bloodstained urine was obtained by catheter.

Immediate Postoperative Stage.—The patient soon regained consciousness and showed no signs of shock. Her pulse-rate was 100 and temperature 99.4°F. She had been started on a course of penicillin 600,000 units 12-hourly and sulphadimidine, but the latter was discontinued after 2 g. had been given, in view of the urinary findings at operation.

1st Postoperative Day.—The patient's general condition was unaltered, but suprapubically the abdomen was tender and slightly rigid; the temperature and pulse-rate were unchanged. During the first 24 hours 105 oz. of fluids was estimated to have been taken by mouth, and 16 oz. to have been lost in vomit; 17 oz. of bloodstained urine, most of which had been secreted early in the day, was passed.

2nd Postoperative Day.—During this day only 4 oz. of urine was secreted, confirming the suppression of urine; this was complete by 9 P.M., when catheterisation showed that the bladder was empty. During this day the fluid intake was restricted to 30 oz.

3rd Postoperative Day.—Cystoscopy and ureteric catheterisation revealed no mechanical obstruction; 5 drops of heavily bloodstained urine was obtained from the right ureter, and none from the left. The urine was sterile on culture and contained several hyaline casts. A Ryle's tube was passed through the nose into the stomach, and an emulsion of glucose 400 g., peanut oil 100 g., and acacia to emulsify in 1 litre of water as recommended by Bull et al. (1949) was dripped slowly day and night. Vomiting occurred once, but most of this was strained through gauze and returned to the intragastric drip.

4th Postoperative Day.—A gastric drip was continued although vomiting occurred on several occasions.

5th Postoperative Day.—Vomiting had by now assumed serious proportions and was causing the patient distress and

ourselves anxiety. In the previous 48 hours she had absorbed little more than 1 litre of the mixture and was noticeably more drowsy. A sensitisation rash, which we assumed was due to penicillin, made its appearance on the thighs, abdomen, and arms, but fortunately the irritation it caused was rendered less disturbing by the patient's continued desire to sleep. A litre of 5% dextrose in water was rapidly infused to restore the fluid balance, and in an attempt to stop vomiting the stomach was washed out with water, and a dilute glucose solution was substituted for the previous mixture. Since no improvement followed, we abandoned all further attempts at gastric feeding.

6th Postoperative Day.—The problem now was how to provide the patient with the necessary calorie value without exceeding a daily fluid intake of 1 litre. Obviously a very hypertonic 40% dextrose solution could not be introduced into a peripheral vein without producing thrombosis and localised oedema. The patient's temperature had been normal for 2 days, and we did not wish to make matters worse by adopting measures which were certain to lead soon to inflammation with its dangers of increased tissue breakdown (Borst 1948). We therefore introduced a cardiac catheter as far as the superior vena cava and dripped through it a 40% dextrose solution day and night, as recommended by de Keyser et al. (1949) and Bull (1952). This provided the patient with at least 1600 calories a day and a basic fluid allowance of 1 litre to offset the insensible loss. At the same time in each 24-hour period the volume of fluid lost by vomiting was accurately measured and balanced by addition to the intravenous infusion of an equal volume of 5% dextrose in water.

Intravenous therapy stopped

During the first five days the recorded quantities of oral fluids and vomit are approximate. Vitamins given from 23rd day onwards. *On these occasions the bottles were changed before they were quite empty; hence the intake did not quite amount to 1000 ml.

10th Postoperative Day.—After 4 days' continuous intravenous therapy, during which the patient remained cheerful and surprisingly well in view of the continued vomiting of small quantities of fluid, thrombophlebitis was noticed along the left basilic vein, with pain, oedema, and reddening of the arm, but unaccompanied by febrile reaction. The catheter was therefore withdrawn on the 4th day of its use and with it a six-inch length of sloughing intima which we presumed had come from the basilic vein. Had the catheter not been withdrawn, the infection would probably have spread to the greater veins of the neck, with serious consequence to the patient (de Keyser et al. 1949). Since the right basilic vein had previously been marred by an unsuccessful attempt to introduce a cardiac catheter, an alternative route had to be considered. The inferior vena cava was chosen; so the right saphenous vein was exposed in the femoral triangle and a 'Polythene' catheter was introduced to a distance of 8 inches. For the next 17 days the patient received fluids and nutrition by this route without any complications arising; and, when the time came to discontinue this form of therapy, the infusion was working as perfectly as it did on the first day of its use. From this day until the 22nd postoperative day insulin was given by subcutaneous injection (table 1).

14th Postoperative Day.—The patient passed 700 ml. of dark murky urine, sp. gr. 1.014, containing numerous red cells, pus, and squamous epithelial cells but no casts or crystals. Her general condition was remarkably good, as it had been throughout the anuric phase, but in the evening she became drowsy and had a febrile reaction with a mild rigor. Her skin was dry, and she complained that her tongue "tasted salty." Next day she was once again free from symptoms, but her temperature rose to 100°F during the succeeding two evenings. Vomiting persisted, and it was therefore necessary to persevere with intravenous therapy.

16th Postoperative Day.—Since the amount of haemoglobin had decreased to 48%, a pint of group-O rhesus-positive packed cells was transfused.

17th and 18th Postoperative Days.—Cautious attempts were made to introduce water and fruit juices by mouth, but this provoked increased vomiting, wherefore we postponed further attempts at giving nourishment orally.

22nd Postoperative Day.—The non-protein-nitrogen level reached its peak at 380 mg. per 100 ml. despite an increase in daily output of urine. About now the patient began to complain of generalised severe pain, principally in the right hypochondrium and in the lumbar regions, for which we could find no cause. Possibly these symptoms were related to renal recovery.

23rd Postoperative Day.—The daily output of urine had almost reached 2 litres, and from now onwards diminishing nitrogen levels in the blood were recorded. The extent of the fall in the level of non-protein nitrogen in the serum on this day (table II) is remarkable but coincides with a reawakening of intestinal function, which up till then had been in complete abeyance. The first motion passed resembled an ordinary constipated stool, but thereafter, and until oral nourishment was resumed, faecal material similar in appearance to meconium was passed in small quantities twice or three times a day. Once again a mild febrile reaction developed, although the patient continued to feel well.

26th Postoperative Day.—Since vomiting had ceased the day before, the patient was encouraged to take nourishment by mouth. At first we only allowed her to sip small amounts of water, soup, and fruit juices, but a more solid diet was gradually introduced over 2-3 weeks.

27th Postoperative Day.—Intravenous therapy was discontinued after 21 days.

The patient's return to health was rapid and uneventful, and 4 weeks later (7 weeks after admission to hospital) she was discharged home. Renal recovery was not yet complete,

for the specific gravity of the urine was low at 1.008-1.010, and the non-protein-nitrogen level in the blood was 72 mg. per 100 ml.

Discussion

The conservative management of anuria has been discussed by Bull (1952), Darmady (1952), and Vest and Kelley (1953), and considerable agreement has been reached on the principles of treatment. It is generally accepted that the anuric patient should be provided with at least 1600 calories a day, to reduce to a minimum the endogenous breakdown of tissues, together with water up to but not exceeding 1 litre, just sufficient to replace the insensible loss. Usually these provisions can be given in the form of an emulsion of glucose and peanut oil in 1 litre of water dripped through an intragastric tube, the technique advocated by Bull et al. (1949). In many cases this form of treatment, though unpleasant for the patient, is tolerated well and is successful, even though on occasion some of the emulsion may be vomited, when it has to be strained back into the intragastric drip. Repeated vomiting or diarrhoea is more serious, though urea and potassium are said to be lost by these routes. In the present case the continued vomiting may have helped towards recovery by getting rid of these substances.

Only when the vomiting becomes persistent will intragastric feeding have to be stopped and be superseded by intravenous therapy. Since only 1 litre of fluid in each 24 hours is permissible, and since this must provide 1600 calories, the concentration of sugar solution, if such a solution is to be chosen, must be at least 40%. Such a solution cannot, however, be run into a peripheral vein for more than a day or so without producing thrombosis; so one of the great veins must be chosen for the infusion if the drip is to be given for any great length of time. The infused hypertonic solution is apparently so quickly diluted by the blood-flow in the large vein that no thrombus is formed. From our limited experience and from discussing this matter with those of our colleagues who are accustomed to cardiac catheterisation we believed that this procedure need not be looked on as formidable or dangerous. Several technical details, however, require further consideration.

PREVENTION OF THROMBOPHLEBITIS

Unless thrombophlebitis is successfully prevented, it may not be possible to continue the only treatment likely to preserve the patient's life. The most scrupulous asepsis must be practised in putting up the drip; and this asepsis must be maintained all the time that the drip is in use. Heparin 15,000 units per 24 hours and penicillin should be added to the infused fluids. Two other factors may help to reduce the incidence of thrombo-

phlebitis: (1) the amount of movement permitted at the point of entry of the catheter and throughout its length should be reduced to a minimum; and (2) the length of vein of small calibre traversed by the catheter should be as short as possible. Infusion into the inferior vena cava has these two merits; therefore we recommend this route rather than the alternative route, into the superior vena cava. If signs of inflammation develop despite these precautions, the catheter must be withdrawn without delay.

INFUSION INTO INFERIOR VENA CAVA

To minimise the risk of infection masks, gowns, and gloves should be worn and full asepsis and antisepsis practised.

The apparatus required is the same as for cutting down on a vein; a transfusion bottle containing the appropriate solution; a polythene catheter 4 mm. in diameter and about 12 inches long; a short piece of thick-walled rubber tubing to fit tightly over the polythene tube; and all connecting pieces (see figure).

A 2-inch incision exposes the upper end of the saphenous vein, whose three or four main tributaries and distal end are carefully ligated. The vein is opened and the polythene catheter passed for 8-10 inches and secured firmly with a double ligature of fine catgut. The following arrangement exerted pressure on the wound not only while the catheter was in situ but also when the time came for it to be removed.

At the time of insertion of the catheter a stout nylon suture (size 8) was passed through the skin, under the saphenous vein $\frac{1}{2}$ inch proximal to the point of entry of the catheter, over the vein, and then under it once more, and brought out through the skin on the opposite side. This suture was securely tied over a small pad of sterile gauze, with its ends left long. When the time came to remove the catheter, the nylon knot over the gauze was loosened; as soon as the catheter was withdrawn, the suture was tightened over the gauze pad rather more firmly than before; this kinked the saphenous vein, thus preventing haemorrhage. The nylon suture was removed by firm traction 72 hours later.

Specimens of blood for biochemical analysis may readily be collected through the polythene tube by temporarily stopping and disconnecting the drip and aspirating blood with a syringe. When the drip is reconnected, as much as possible of the blood remaining in the tube should be flushed back into the circulation without delay by momentarily racing the drip; otherwise a thrombus may form in the tubing.

INFUSION INTO THE SUPERIOR VENA CAVA

For catheterisation of the superior vena cava certain additional points in technique must be observed. The catheter should be of the type normally used for cardiac catheterisation; the median antecubital vein, preferably the right, is exposed and the catheter inserted first into the basilic vein, thence into the subclavian vein, and onwards under the fluorescent screen into the superior vena cava. Sometimes the tip of the catheter enters the wrong vein, especially the internal jugular vein. When this happens, it should be partially withdrawn and the patient's arm abducted and rotated before the catheter is reinserted. The tip of the catheter should not remain in either the jugular or the subclavian vein, because the continued use of hypertonic solutions may cause them to thrombose (de Keyser et al. 1949).

CONTROL OF INTRAVENOUS THERAPY

In the present case 1 litre of 40% dextrose was infused daily together with such additions as were required to make up fluid lost in vomit or urine. For convenience, the additions consisted of 5% dextrose in water.

The correction of electrolyte deficiency during anuria is not normally practised (Bull et al. 1950) and therefore we were reluctant to give saline solution, but after a very careful day-to-day tally of the amounts of sodium chloride lost by vomiting it became clear on the 14th postoperative day that a real deficit amounting to nearly 9 g. existed. Moreover, at this time the sodium and chlorine levels in the serum were somewhat lower than they had been; therefore 4 g. of sodium chloride was added to the dextrose drip. Next day diuresis began, and thereafter we had no hesitation in adding to the

Distal end of polythene tube which was passed through right saphenous vein into inferior vena cava, and through which continuous infusion was maintained for seventeen days without producing any complication.

infusion amounts of saline equal to, but never in excess of, the chlorine and sodium deficit at the time.

Table II shows that the serum-potassium level during the anuria remained at fairly constant low values and never exceeded 22 mg. per 100 ml. Small amounts of potassium chloride were introduced into the drip on three occasions during the recovery period, during which the serum-potassium levels fluctuated from 17 to 22 mg. per 100 ml.

Ketosis and acidosis did not develop—a fact which is all the more remarkable when it is remembered that for 3 weeks the patient was given nothing by mouth and throughout this time vomiting continued without respite.

HANDLING OF BIOCHEMICAL DATA

Since the patient's life appeared to depend on the careful recording and assessment of biochemical results, and on a meticulous regard to detail in many small but important practical matters, the following programme of management was evolved.

Samples of blood with the 24-hour collections of either urine or vomit or both were dispatched for analysis each day at 9.30 A.M. The laboratory findings in these specimens were telephoned back to the ward by 2.30 each afternoon; and all results so notified were received and recorded immediately either by one of us (J. C. B.) or by the ward sister.

Biochemical and fluid deficits were calculated from the daily laboratory results, and from these the nature and amount of extra parenteral fluid therapy for the succeeding 24-hour period was estimated. For convenience this 24-hour period always began at 3.30 P.M.

Except for a few days, one of us (J. C. B.) accepted the responsibility for the close handling and scrutiny of the biochemical data, and for the control of the intravenous therapy. This arrangement was an important factor leading to our patient's recovery.

Summary

The principles to be adopted in the treatment of anuria are briefly considered.

The successful management of prolonged anuria (complete for 11 days, partial for a further 10 days), following septic abortion is described in detail.

The limitations of oral feeding for anuric patients with gastric intolerance are emphasised. In the present case excessive vomiting precluded the continuation of feeding by intragastric tube. The patient's nutritional requirements were effectively supplied for 21 days by the intravenous administration of dextrose 400 g. daily. Over-hydration was prevented by infusing a 40% solution of dextrose at first into the superior vena cava and later into the inferior vena cava.

The two techniques of infusion into the superior vena cava and into the inferior vena cava are neither difficult to perform nor particularly distressing to the patient. For reasons discussed here we prefer infusions into the inferior vena cava, and in the present case we maintained the infusion into this vein for 17 consecutive days without complication.

We believe that infusion of a 40% glucose solution into one of the great veins may have a wider application than hitherto in the treatment of patients who cannot obtain nourishment through the alimentary tract; but this method may not achieve what is hoped for it, unless the electrolyte and fluid balance is carefully assessed daily and close attention is given to the management of the infusions. If this can be done by one and the same person, so much the better.

We wish to thank Mr. F. J. P. O'Gorman, F.R.C.S., for his cystoscopic examination of our patient, Mr. B. W. Auchinachie, F.R.D., and his staff for the daily biochemical analyses, and Dr. F. W. Leigh, of the cardiovascular department of the Hospital, for his assistance with the intravenous infusions, and Sister Mitchell and the nurses for their invaluable help.

THE careful administration of hexamethonium bromide (H.M.B.) and its homologues is probably the most effective treatment at present available for arterial hypertension, and with it a great measure of improvement may be obtained in almost all patients. Papilloedema, where present, disappears in almost all adequately treated cases, and reduction in heart size is common (Smirk 1953b and c). Improvement can be seen in the electrocardiograms in most cases (Doyle 1953). In most cases, congestive heart-failure or left ventricular failure can be relieved without the use of digitalis, mersalyl, or salt-free diet (Smirk 1953c).

Many hypertensive patients suffer from angina pectoris. In some series the proportion is as high as 20% (Schottstaedt and Sokolow 1953), while 13% of the 1264 hypertensive patients reviewed by Goldring and Chasis (1944) died of coronary thrombosis.

Hayward (1952) has suggested that the reduction of aortic diastolic blood-pressure produced by effective treatment with the methonium compounds may lead to a decrease in coronary blood-flow, and hence to myocardial ischaemia or to cardiac infarction. Morrison (1953) preferred not to use these compounds in treating hypertensive patients with angina. There is some evidence that myocardial ischaemia may sometimes follow reduction of the blood-pressure. Lindgren and Frisk (1948), for example, reported prolonged precordial pain in 3 anginal patients and coronary thrombosis in a 4th after the blood-pressure had been reduced by tetraethylammonium chloride. In an earlier publication from this department (Smirk and Alstad 1951) it was reported that methonium salts should be administered to anginal patients very cautiously, but that improvement was detectable in some patients.

Test injections of H.M.B. or similar substances have now been given here to over 450 patients, of whom 250 have been treated for long periods. Of the 450 patients who have had test injections, 50 had angina pectoris. 40 of these have been treated for three months or more with a methonium compound.

We report here the effects of test injections and prolonged treatment in these hypertensive patients with angina, with particular reference to spontaneous chest pain resulting from reduction of blood-pressure and the effects of treatment on the severity of the angina.

Case-numbers correspond with those in earlier publications (Smirk and Alstad 1951, Kilpatrick and Smirk 1952, Doyle 1953).

Methods

Selection of Patients

All patients with angina whose casual systolic blood-pressure was over 160 mm. Hg. and who received test injections of H.M.B. or related compounds have been included in this series, and all such patients who were

referred to the clinic have been tested to avoid errors of selection. Angina was diagnosed by one of us, and where there was doubt separate opinions by each have been obtained. Only patients in whom the pain was agreed to be undoubtedly anginal have been included in this series.

Method of Treatment

Patients were weighed at each attendance. No form of therapy was given until a methonium compound had been tried. Test injections were made subcutaneously and the blood-pressure was recorded in the standing and sitting positions at half-hourly intervals. Treatment in most patients has been by subcutaneous injection of H.M.B. Oral treatment was effective in 13 patients, and these were given hexamethonium bitartrate by mouth or 'M. & B. 2050A' by mouth. A few have been treated with M. & B. 2050A by subcutaneous injection (Smirk 1953a). The initial dose of H.M.B. used was 7.5 mg., while the initial subcutaneous dose of M. & B. 2050A in polyvinylpyrrolidone (P.V.P.) was 2 mg. The initial dose of M. & B. 2050A by mouth was 20-40 mg. Our methods of control of treatment with these substances have been described elsewhere (Smirk 1953b). In treating patients with angina we have taken additional precautions. Initial doses were half of those usually given to other hypertensive patients. The dose was then raised daily with close supervision until a dose was reached which reduced the systolic blood-pressure in the standing position to about 140 mm. Hg, provided that there had been no spontaneous chest pain before this point was reached. Careful watch was kept for such pain, and immediately it was felt the patient was made to lie down. This relieved the discomfort at once. Spontaneous chest pain associated with falls in blood-pressure was always regarded as indicating that the limit of safe dosage and of blood-pressure reduction had been exceeded. Occasional mild attacks of spontaneous chest pain were regarded as an indication, not for stopping treatment but rather for reducing the dose.

Results

SEVERITY OF ANGINA

Of 50 patients with definite angina, 10 refused, or were thought unsuitable for, prolonged treatment. The remaining 40 patients have been treated with one of the methonium compounds for three months or more. The longest period of treatment has been three and a half years. The average time of treatment for the 40 patients was ten and a half months.

In 11 of the 40 patients the pain has disappeared altogether, and all of these patients are much more active than before treatment was given.

In a further 22 patients the severity of the angina has been reduced, so that most are able to take more exercise with less frequent pain. Several have returned to work, and some have been able to lead almost normal lives.

The remaining 7 patients were unimproved by treatment.

The effort tolerance did not appear to be reduced in any of the patients treated. Those in whom spontaneous chest pain developed are referred to below.

Improvement in the angina is rare with less than about a week's treatment and may not take place for up to a month. Benefit is usually greatest by the end of the third or fourth month of treatment, and further improvement after this period is unusual. Relapses of pain do not seem to occur provided that doses producing adequate falls of blood-pressure continue to be taken.

Accuracy of dosage is most important, since doses which cause excessive falls of blood-pressure may produce spontaneous chest pain, while doses followed by ineffective falls of blood-pressure do not often improve the effort tolerance.

The following are some of the cases in which improvement took place.

Case 343.—A man, aged 66, was first seen in November, 1952. There had been severe angina of effort for three months, but no protracted attack of pain. For several years he had had headache and giddiness and there had been some dyspnoea on exertion. The blood-pressure was 200/120 mm. Hg; the fundi showed grade-II changes (Wagener and Keith 1939); the electrocardiogram showed grade-III (advanced hypertensive) changes (Doyle 1953); and radiography showed no cardiac enlargement.

Treatment was started in January, 1953. Within a week his effort tolerance was considerably improved, and the patient could walk very much further with less frequent pain. The improvement continued, and when seen in May he said that his activity had returned to normal and there had been no further pain. He was seen again in July, when he said that there had been some recurrence of pain after he had reduced the dose because of dryness of the mouth. On restoring the dose to its previous level the pain disappeared again. When last seen (in October) he was free of pain and was more active than before treatment.

Case 52.—A woman, aged 45, was first seen in June, 1948, with a blood-pressure of 248/140 mm. Hg. She complained of severe headaches of many years' duration, attacks of giddiness, and shortness of breath and anginal pain on effort for the past year. The heart was much enlarged; and there were many retinal hemorrhages, some exudate, retinal oedema, and an ill-defined edge to the disc. She was admitted to hospital in December, 1949, when the blood-pressure was 260/180 mm. Hg. There were frequent attacks of left ventricular failure and breathlessness at rest, and she was almost bedridden. There was advanced papilloedema. The angina had been severe for two and a half years.

Treatment with H.M.B. was started. Within two months headache, breathlessness, and the dizzy attacks had disappeared, and within six months the papilloedema had cleared. Until April, 1951, the patient lived a substantially normal life, apart from the injections, and had no chest pain or breathlessness with moderate activity. She died in April, 1951, of a cerebral haemorrhage. Post-mortem examination showed that the heart was much enlarged (weight 575 g.), the enlargement being almost entirely due to left ventricular hypertrophy. The coronary arteries were widely patent, and although there was some concentric intimal thickening there was no gross atherosclerosis. There was no evidence of myocardial infarction.

Case 704.—A woman, aged 66, was admitted to the Dunedin Hospital in April, 1953. She had had typical angina for fifteen years, and for the last year the attacks had come on with the slightest exertion and sometimes in bed. The electrocardiogram showed grade-III changes; the basal blood-pressure was 222/124 mm. Hg, and radiography showed considerable left ventricular enlargement.

Treatment was started with M. & B. 2050A in P.V.P. by subcutaneous injection. The patient was last seen in September, 1953. Since treatment had been begun there had been two long attacks of severe precordial pain starting in the early hours of the morning. These were associated with attacks of abnormal rhythm which the electrocardiogram showed to be ventricular tachycardia. Generally speaking, she was much improved. There had been no other attacks of pain at rest, and she could do considerably more with less frequent pain.

Case 708.—A woman, aged 46, was first seen in September, 1950, with a history of angina of effort for eighteen months. The pain came on with slow walking up a slight hill. The casual blood-pressure was 210/130 mm. Hg. The electrocardiogram was normal at rest but showed distinct depression of the S-T segment in the left-sided precordial leads after exertion.

The patient was treated with hexamethonium bitartrate by mouth, and doses of 1 g. reduced her blood-pressure to about 140/90 mm. Hg. She was last seen in October, 1953, when there was no pain on ordinary activity; she could walk up moderate hills and ride a cycle to work without pain. The electrocardiogram had not improved.

Case 712.—A man, aged 55, was first seen in the outpatient department in March, 1953. He had had angina of effort for six weeks. There had been no severe attack, but the electrocardiogram showed right branch bundle block with distinct S-T-segment depression over the left-sided precordial leads.

Treatment was started in June, 1953; and he was last seen in October. At this time he said that he still had pain on hills and on the level against a wind. He could ride some three-quarters of a mile on a bicycle before the pain came on, whereas before treatment he could not do more than two hundred yards. Although clinical improvement was considered to be doubtful and the electrocardiographic pattern of right branch bundle block was unchanged, the s-t-segment depression previously present had disappeared. Treatment was difficult in this patient because of spontaneous pain when the systolic blood-pressure fell below about 150 mm. Hg.

SPONTANEOUS CHEST PAIN

Of the 50 patients with angina who have had test injections or prolonged treatment, 13 had spontaneous chest pain during the period of blood-pressure reduction. In addition, a further 2 patients who had never previously noted angina had spontaneous anginal chest pain when the blood-pressure was reduced. We believe that the smallness of the proportion of patients who have had such spontaneous pain is largely due to careful supervision of treatment.

The blood-pressure level at which spontaneous pain develops varies from patient to patient. Most do not get spontaneous pain unless the systolic blood-pressure falls below about 120 mm. Hg; but in some patients (for example cases 712 and 143) spontaneous chest pain occurred at rather higher levels, case 143 complaining of pain when the systolic pressure fell to 180 mm. Hg. In 2 patients spontaneous chest pain has occurred in association with paroxysmal tachycardia—in one of ventricular type, in the other of auricular type. We have had the impression that spontaneous pain is more likely in the early stages of treatment, although it may occur at any stage if doses causing excessive falls of blood-pressure are given. In some patients the pain seems to be caused by the abrupt falls of blood-pressure, and this may occasionally be avoided by giving oral preparations or slowing agents to delay the fall of blood-pressure (Smirk 1952). In some patients, however, the effects of oral administration are too unpredictable for accurate control of treatment, since capricious alimentary absorption may lead to occasional excessive falls of blood-pressure.

Treatment had to be discontinued in 5 patients (cases 139, 143, 176, 197, and 719) because of spontaneous chest pain.

Case 139.—A woman, aged 67, was admitted to the Dunedin Hospital in February, 1951, with a history of dyspnoea on exertion for four years and angina of effort for three years. On clinical examination there was moderate cardiac enlargement. The casual blood-pressure was 190/130 mm. Hg. The electrocardiogram showed grade-III changes.

Treatment with oral hexamethonium bitartrate was begun, but this had to be discontinued after a month because of diarrhoea, and treatment by subcutaneous injection was substituted. There was slight improvement in the severity of the angina after two months' treatment, but at the end of this time the patient had a long attack of chest pain. It was thought that this attack probably followed an overdose of the drug since the patient had not understood the instructions for dosage. The treatment was discontinued because of the onset of presenile dementia.

Case 143.—A woman, aged 53, was admitted to the Dunedin Hospital in February, 1951. She had been treated for angina of effort for five years, and cardiac infarction had occurred four years previously. On admission there was clinical and radiographic evidence of gross cardiac enlargement. The casual blood-pressure was 268/130 mm. Hg, and the basal blood-pressure was 210/118. The electrocardiogram showed grade-III hypertensive changes.

A subcutaneous injection of 20 mg. of H.M.B. reduced the blood-pressure to 196/98, at which level the patient complained of pain in the chest. An injection of 0.9% saline the next day also produced an attack of pain with the blood-pressure at 218/106 mm. Hg. Treatment was discontinued because of the ease with which pain occurred and because the patient was particularly apprehensive and suggestible.

Case 176.—A man, aged 49, was first seen in 1946 with angina of effort following a myocardial infarction. The angina persisted, and he was seen again in July, 1951. The casual blood-pressure at this time was 210/120 mm. Hg. It was decided to assess the effects of H.M.B.

The blood-pressure could be reduced to 116/90 mm. Hg without the development of spontaneous chest pain. With administration of H.M.B. there seemed at first to be some subjective improvement, but at the end of two months the angina was substantially as severe as before. At about this time the patient had a severe attack of spontaneous chest pain, and, since improvement had been slight, treatment was discontinued. He continued to have angina until his death from another cardiac infarction fifteen months after stopping treatment. Necropsy revealed severe coronary sclerosis with a recent anterior myocardial infarction and an old posterior infarction.

Case 197.—A woman, aged 58, was first seen as an outpatient in May, 1951, with complaints of headache and giddiness. There was no angina at this time. The casual blood-pressure was 250/140 mm. Hg. There was no clinical evidence of cardiac enlargement, and the fundi showed grade-II changes. The basal blood-pressure was 162/114 mm. Hg. The electrocardiogram showed advanced hypertensive changes.

Treatment by subcutaneous injections of H.M.B. was started in August, 1951, but a month later the patient was readmitted after a long attack of chest pain which was due to coronary insufficiency; the pain had come on six hours after the last injection of H.M.B. Treatment was discontinued at this time, but the patient was readmitted in December, 1951, with congestive heart-failure. The casual blood-pressure at this time was 212/152 mm. Hg. The failure was rapidly overcome by administration of H.M.B., and this treatment was continued without further incident until May, 1952. At this time the patient was readmitted with severe bronchopneumonia. Treatment was again discontinued and was not subsequently recommenced. She died in September, 1952, of a cardiac infarction. There was no necropsy.

Case 719.—A woman, aged 42, was seen as an outpatient in January, 1953, with a history of angina of effort for three years and of cardiac asthma for three months. The casual blood-pressure was 175/110 mm. Hg. There was no clinical or radiographic evidence of cardiac enlargement, and the electrocardiogram at rest was normal, although there was depression of the s-t segment in the left-sided precordial leads after exercise.

Treatment with oral hexamethonium bitartrate was started. There appeared at first to be some improvement, but this was never very great. Three months after treatment was started severe diarrhoea developed, and treatment with subcutaneous H.M.B. was substituted. The patient proved extremely sensitive to the drug, and 7½ mg. subcutaneously reduced the blood-pressure to 110/70 mm. Hg and spontaneous chest pain occurred. In view of doubt about the improvement and the spontaneous chest pain, treatment was discontinued. The angina has since persisted.

CARDIAC INFARCTION

Of the whole series of 450 patients, 10 have had cardiac infarctions. Of these, 4 were under treatment at the time of the infarction and the remaining 6 were not being treated. In each of the untreated patients the infarction was fatal. 2 of the patients who were under treatment recovered from the infarction, but both died from subsequent cardiac infarction before treatment had been recommenced. In only 1 patient did cardiac infarction occur at a time when the blood-pressure was low as the result of administration of H.M.B. In the remaining patients the pain started when the blood-pressure would normally have risen after the previous injection. We have the impression that careful treatment with these substances, producing moderate falls of blood-pressure, does not lead to cardiac infarction even in patients with angina. We have ordinarily not treated patients with these substances if cardiac infarction has occurred in the preceding six weeks.

Discussion

The normal ratio of cardiac work to coronary blood-flow is disturbed in patients with angina (Wégria 1951).

It is apparent that arterial hypertension increases the cardiac work. Blumgart et al. (1940) and Davis and Klainer (1940a, b, and c) demonstrated, in studies of the relation of the clinical manifestations of angina and myocardial infarction to the pathological findings, that some patients with clear-cut angina had normal coronary arteries, the heart being considerably hypertrophied because of hypertension or valvular disease. Harrison and Wood (1949) concluded from a study of hypertensive patients with angina that in many there was coronary dilatation rather than narrowing, so in these the main cause of the angina seemed to be increased cardiac work. In the present series some of the cases examined post mortem showed no evidence of coronary arterial narrowing.

There is little doubt that in the hypertensive patient reduction of the blood-pressure appreciably reduces cardiac work. In those patients with hypertension who obtain relief from angina after reduction of the blood-pressure, it seems probable that the reduction in cardiac work is greater than the reduction in coronary blood-flow when the aortic blood-pressure falls. In a few patients, however, with moderate falls in blood-pressure the reduction of the mean aortic diastolic blood-pressure, and hence of coronary blood-flow, may exceed the reduction of cardiac work so that spontaneous chest pain occurs. In our experience, such a sequence is unusual if the fall of blood-pressure is carefully controlled. We have had the impression, however, that if the blood-pressure is allowed to fall excessively spontaneous chest pain will occur in a larger proportion of patients. The level of blood-pressure at which such pain occurs can be determined in the individual patient only by the most circumspect increments after a small initial dose.

In practice, therefore, angina pectoris complicating hypertension need not be a contra-indication to the use of the methonium compounds. Indeed, the use of those compounds seems to be indicated, provided that they are administered very cautiously. For the ordinary hypertensive patient the fall of blood-pressure in the standing position should be such that recumbency will immediately restore the pressure to about the original level, and it is essential that this precaution be observed in treating the hypertensive patient with angina. This entails frequent observation of the patient in the preliminary period of stabilisation, and critical adjustment of dose; this can be achieved only by the use of syringes graduated to 0.01 ml. Furthermore, the standing systolic blood-pressure should not be reduced below 140 mm. Hg, at least in the preliminary period of treatment when attacks of coronary pain are commonest. We have the impression that spontaneous pain is less likely if the blood-pressure is reduced slowly by the use of delaying agents and sometimes by oral therapy. Oral H.M.B. is, however, not often successful (Kilpatrick and Smirk 1952) and even patients who can take adequate doses by mouth without prohibitive side-effects may have excessive falls of blood-pressure because of the irregular effect of administration by this route.

It has not been possible in the present series to assess the placebo action of these drugs in relieving angina. It is well known that angina can commonly be relieved by placebos. The improvement in other symptoms of hypertension after hypotensive therapy, with the induction of hypotensive symptoms, makes it difficult to substitute ineffective therapy without the patient's knowledge. The main object of treatment in our patients, however, has not been so much the relief of angina as the control of the hypertension in general; and in most cases the angina has been one of numerous symptoms. We have the impression that the striking improvement which occurs gradually over a period of several months can be more reasonably attributed to the reduction of blood-pressure than to a placebo action.

Summary and Conclusions

The methonium compounds may be safely administered to hypertensive patients with angina, with close supervision by experienced physicians and well-trained technical assistants.

The effects of reducing the blood-pressure by this means have been studied in 50 cases. About a quarter of the patients had occasional attacks of spontaneous chest pain and in 5 treatment had to be stopped because of such pain after modest falls of blood-pressure.

A third of the patients treated lost all angina after some months' treatment, while two thirds of the remainder were much improved in this respect.

Cardiac infarction was no commoner in treated patients than in similar untreated patients.

We are indebted to Prof. F. H. Smirk for much helpful advice and criticism. We wish to thank also Miss B. Hoare, Miss B. Stanton, and Miss O. Fraser without whose technical assistance at the hypertensive clinic these observations would not have been possible. We are indebted to Miss N. Richardson and Miss M. Poppelwell for secretarial help. The hexamethonium bromide and related compounds were supplied by Messrs. May & Baker Ltd., Dagenham, Essex.

PORPHYRIA TREATED WITH NEOSTIGMINE

R. O. GILLHESPY

M.D. Edin., F.R.C.P.E.

PHYSICIAN TO THE DUDLEY ROAD GROUP OF HOSPITALS,
BIRMINGHAM

S. G. SMITH

B.Sc. Birm.

BIOCHEMIST, DUDLEY ROAD HOSPITAL, BIRMINGHAM

We have recently studied a case of porphyria combining clinical and biochemical features not hitherto described in this disease. The patient recovered after treatment with neostigmine. Successful therapy of porphyria with this drug has not previously been described.

The presenting clinical features were (1) severe colicky abdominal pain associated with nausea and vomiting; (2) dark urine; (3) progressive loss of weight producing emaciation (fig. 1); (4) progressive weakness of the limbs; (5) hoarseness; and (6) hirsuties (fig. 2).

Case-report

A woman, aged 37, was apparently perfectly well until January, 1951, when she was admitted to a general hospital in the West Country with severe generalised lower abdominal pain accompanied by nausea and vomiting. The diagnosis of acute appendicitis was not substantiated at operation, nothing abnormal being discovered. After this operation the patient lived in Jersey, and continued to have severe colicky abdominal pain, constipation, rectal discomfort, frontal headaches, and intermittent bouts of pyrexia. After returning home, and while she was working as a supervisor in a large café,

these symptoms became so severe that she was admitted to a large general hospital for investigation. In hospital she passed dark urine and her voice became husky. Nervous dysfunction of the bowel was diagnosed, and the patient was discharged. Late in September, 1951, she was readmitted to the West Country hospital. She became depressed and tried to commit suicide by taking gr. 18 of soluble phenobarbitone. She was transferred to a mental hospital and shortly after admission complained of numbness and weakness in the limbs. Electroconvulsion therapy was ordered, and immediately afterwards both legs became useless. After seven days the treatment was repeated, and next morning her arms as well as her legs were useless. Deterioration in her general condition continued, and on Feb. 9, 1952, she was taken home by her relations and within a few days was admitted to this hospital.

On examination gross emaciation of all the muscle-groups throughout the body was apparent, a thick growth of hair covered most of the body, especially the face, and there was slight exophthalmos (figs. 1 and 2). The blood-pressure was 120/90 mm. Hg. The heart-rate was increased, and the apex-beat was felt in the fifth intercostal space $3\frac{1}{2}$ in. from the midline. Nothing abnormal was detected in the respiratory system and abdomen. All the cranial nerves except the tenth were normal. Paralysis of the right recurrent laryngeal nerve caused complete inability to move the right vocal cord. The arms and legs could not be moved. The tendon-reflexes were all present, and the plantar responses were flexor. There was no impairment of sensation.

Investigations.—A full biochemical, bacteriological, and cytological examination of the cerebrospinal fluid, including a Wassermann reaction and Lange curve, revealed no abnormalities. Examination of the blood gave a normal electrolyte pattern, calcium and phosphorus, glucose-tolerance test, urea, gonococcal fixation test, and blood-count; liver-function tests were also normal, as was the calcium in urine and faeces, and the basal metabolic rate. The blood-cholesterol level was raised on admission but dropped to normal on discharge.

Fig. 1.—Emaciation and hirsuties of thighs on admission.

Urinary creatinine excretion was somewhat depressed, whereas creatine excretion was raised. Examination of bone-marrow revealed that the erythropoietic system was active, and many macronormoblasts were seen. None of the red-cell precursors were megaloblastic. The white-cell maturation was normal. Radiography of the chest and lumbar spine showed no abnormalities, whereas radiography of the hands showed osteoporosis of the carpus and metaphyses of the bones, suggesting osteoporosis due to disuse. The electrical reaction of the muscles was normal to faradism and galvanism, and no myasthenic reaction was present. A biopsy specimen showed an increase of nuclei and small collections of lymphocytes between the muscle-fibres, with atrophy of the muscle (this is the essential appearance of myasthenia gravis). An electrophoresis pattern of the serum-proteins showed a very slightly raised gamma-globulin level.

The urine became pinkish red on standing and on treatment with hydrochloric acid, and gave a pink fluorescence in ultraviolet light. Examination of the spectrum of a 25% solution of hydrochloric acid in the urine showed bands at 5956 and 5520 Å, the spectrophotometric absorption pattern being characteristic of an acid porphyrin solution. Ehrlich's reagent gave with the fresh untreated urine a pink colour which could

Fig. 2.—Exophthalmos and facial hirsuties on admission.

not be extracted with amyl alcohol. Porphyrin was therefore established. The urine-uroporphyrin levels were quantitatively estimated during four phases of the patient's stay in hospital. Levels of up to 10 mg. a day were found during the first fortnight, although accurate estimates were made difficult because of the patient's bed-wetting. After two, eight, and ten months the average daily level during a week's excretion was 1.41, 2.85, and 2.11 mg. a day respectively. The peak excretion was noted during menstruation. From its behaviour in ethyl acetate solution, the uroporphyrin appeared to be type I. The urine-coproporphyrin levels were also estimated and varied between 0.1 and 1.0 mg. a day. Column chromatography of an extract from a six-day collection of faeces showed the presence of coproporphyrin plus a decarboxylic porphyrin.

Treatment of Porphyrin.—The treatment of porphyrin is empirical; but, since the histological picture of the muscle was similar to that associated with myasthenia gravis, neostigmine 1 mg. was injected subcutaneously three times a day, with a remarkable response. Within half an hour of the first injection the patient moved her arms and legs easily, and her voice, hitherto very hoarse and faint, became stronger and clearer. She sat up without assistance for the first time since the electroconvulsion therapy in November, 1951. This improvement gradually declined until the next dose was given. Ashby (1924), Gray (1924), Schmidt-Labaume (1926), and Mackey and Garrod (1926) reported that a megaloblastic picture is sometimes present in porphyrin and that injections of liver extract proved helpful. The presence of macronormoblasts in the marrow may have been due to subnormal amounts of the liver factor; so 'Anahæmin' 2 ml. weekly was given. After a few weeks of this treatment the marrow became normoblastic. The patient's general condition improved steadily, and after a month she could sit comfortably without support on the edge of the bed and could move her right arm across the body and touch the tip of her left shoulder. As her strength increased, her ability to turn in bed returned. After seven weeks distilled water was substituted for the neostigmine, and within a few hours the muscles became stiff, and control of the arms and legs was lost. When neostigmine was given again the symptoms rapidly disappeared. After a few more weeks' therapy the voice became clear and strong, and crossing and recrossing of the legs became possible. Small

Fig. 3.—Patient after full recovery.

objects could be placed in the mouth, and the patient ate without assistance. After pronation of the wrists returned, ability to write and to turn the pages of a book soon followed. Steady improvement continued, and walking with mechanical devices on the limbs began after ten months, enabling the patient to be discharged from hospital.

Follow-up.—A rehabilitation course was arranged, and tuition as a telephone operator (one of her former occupations) was given. Recently she omitted the neostigmine for four days and listlessness, acute abdominal pain, and nausea returned but quickly disappeared when neostigmine was taken again. The patient has now fully recovered (fig. 3).

Discussion

Treatment with neostigmine was tried because the histological appearance of the muscle resembled that of myasthenia gravis. The favourable result cannot be doubted, because there was an immediate improvement in the muscle power and well-being, with a relapse when distilled water was substituted for the neostigmine. Further, a relapse occurred when the patient omitted neostigmine after discharge. This favourable response might be explained by a coexistence of a constitutional defect leading to porphyria and of myasthenia gravis, the improvement being due to the influence of the neostigmine on the myasthenia. This hypothesis is supported by the fact that the patient continues to excrete as much porphyrins in her urine and faeces as before the start of therapy; but the absence of other signs and symptoms of myasthenia gravis makes this argument unlikely.

The finding of porphobilinogen in the urine leads to the diagnosis of acute porphyria, although the presence of uroporphyrin I is more in keeping with congenital or mixed porphyria.

Hirson (1953) reports two patients with acute porphyria who recovered spontaneously. Therefore the start of neostigmine therapy in the present case may have coincided with a natural remission of the porphyria, but the return of the symptoms after the withdrawal of neostigmine on two occasions is against this argument.

We therefore think that there was a response to neostigmine and urge that this drug be tried when porphyria has been diagnosed.

As in previous cases, barbiturates had been taken before acute porphyria was detected.

Physiotherapy and rehabilitation considerably helped the patient's recovery.

Summary

A patient with acute porphyria exhibited unusual clinical features, including paralysis of the left recurrent laryngeal nerve, deterioration in the clinical condition following electroconvulsion therapy, hirsuties, lymphocytic infiltration of the muscles, and the presence of uroporphyrin I and porphobilinogen in the urine.

The patient recovered when treated with 1 mg. of neostigmine given subcutaneously three times a day and later by mouth in 10 mg. doses.

We thank Dr. W. Whitelaw, director of pathology, and Miss H. Trought, chief biochemist, to the Dudley Road Group of Hospitals for advice and suggestions; Prof. C. Rimington, F.R.S., of University College Hospital, London, for kindly sending us a solution of coproporphyrin; Mr. H. G. Sammons, Ph.D., of Queen Elizabeth Hospital, Birmingham, for permission to use the Beckmann spectrophotometer; and the staff of the Dudley Road Hospital photography department for their coöperation.

NEW LIVER-FUNCTION TEST

KARL CLOSS

Ph.D., B.M.S.

PROFESSOR OF PHARMACOLOGY, UNIVERSITY OF BERGEN

From the Central Laboratory, Aker Hospital, Oslo, Norway

THE number of so-called liver-function tests has greatly increased, and the older mercuric-chloride tests (Takata-Ara, Gros, &c.) have been superseded by more sensitive and more convenient means of discovering damage to the liver parenchyma. All these tests reveal abnormalities of the serum-proteins—e.g., in parenchymatous liver disease the γ and β globulins are usually increased and are precipitated more easily, and the albumins exert less protective action than is usual—and all have one feature in common: they give precipitations (produce turbidity or flocculation) in pathological sera but none in normal sera.

When chloranilic acid (2:5-dihydroxy-3:6-dichloroquinone), which precipitates protein, was tried in sera from different cases, including some of liver damage, it did just the opposite: it formed a precipitate in all normal sera and in all sera that gave a negative Takata-Ara test. In the sera where the Takata-Ara reaction was positive the more strongly positive the Takata-Ara reaction the less protein was precipitated by

* 1, Usual reagent. 2, Reagent without acetic acid. 3, Reagent with 5 drops of 10% sodium-carbonate solution instead of 0.2 ml. of glacial acetic acid. 4, Reagent with 1.0 ml. of glacial acetic acid.

chloranilic acid, there being no precipitation at all in the most strongly positive sera.

The new reaction was investigated in the Central Laboratory, Aker Hospital, for over a year and then taken into use as our routine method. The results obtained with this method compare very favourably with those given by the Takata-Ara test. Since the new test offers several advantages in simplicity and rapidity, I describe it here.

Method

Reagent	Parts
Chloranilic-acid solution 0.1% (w/v)	70.0
Sodium-chloride solution 0.85% (w/v)	5.0
Glacial acetic acid	0.2
Distilled water ad	100.0

The pH of this mixture is about 2.50. The reagent keeps almost indefinitely if stored in the ice-chest but deteriorates slowly at room-temperature and when exposed to light.

Procedure

To 2 ml. of the reagent in a small test-tube 0.1 ml. of serum is added, and the whole is mixed well. Precipitation usually takes place in a few minutes and is practically complete within 15–30 minutes. Readings can therefore be made after half an hour, but the precipitates must then be thrown down by centrifugation. Alternatively the samples may be left to stand overnight for sedimentation. Both these methods have been used and usually

give identical results. The following grading of the readings was used :

Precipitate	Supernatant fluid	Grading
Heavy	Clear	-
Heavy	Opalescent	(-)
Less heavy	Turbid	(+)
Small	Very turbid	+
Trace	Very turbid	++
None	Translucent	+++

Usually there is no difficulty in assessing the results, but occasionally it is not easy to decide whether a test is positive or not. In some very rare cases the reading after 30 minutes differs from that obtained after 24 hours. These cases include both normal sera which do not precipitate at once and pathological sera which give "false" precipitations on standing.

Since part of the chloranilic acid is precipitated with the protein, a more quantitative assessment may possibly be made by determining the amount of chloranilic acid (which is a dye) colorimetrically in the precipitate and/or in the centrifugate after treatment with trichloro-acetic acid.

Results and Discussion

For the selectivity of the test the pH of the reagent seems to be important. The influence of the pH (table I) was studied in the following way :

In 5 serum samples the test was made with the usual reagent (reagent 1). 3 of the tests were negative, 1 was read as +, and 1 as ++.

When a reagent was used which contained 1.0 ml. of glacial acetic acid instead of 0.2 ml. (reagent 4) +++ reactions were obtained in all the sera tested. The pH of this reagent was 2.44, and a pH of 2.86 was found in the mixture in the case of serum 1.

The substitution of 5 drops of 10% sodium carbonate for the glacial acetic acid (reagent 3) increased the pH of the reagent to 2.75, and of the mixtures of serum and reagent to 3.88 and 3.83; and the test, which had been positive in both sera, became negative. If the glacial acetic acid was omitted from the reagent (reagent 2), the change of pH in the reagent was only slight; it was larger in the mixture, and the test became decidedly less positive with serum 1.

As can be seen from table I, a relatively slight increase in pH of the reagent caused all the positive tests to become negative, whereas a decrease in pH had the opposite effect.

The possibility that the difference observed between normal and pathological sera was due to a difference in the final pH of the mixture was ruled out by measuring the pH in the centrifugates from tests made on 17 samples (table II). For comparison, in 13 of these cases readings with the Takata-Ara test are listed.

The pH in the 9 negative samples ranges from 2.93 to 3.19 (av. 3.07) and in the 8 positive ones from 2.96 to 3.09 (av. 3.04). The difference (if any) between the

TABLE III—CORRELATION BETWEEN CHLORANILIC-ACID AND TAKATA-ARA TESTS IN 120 BLOOD SAMPLES FROM 25* PATIENTS

Chloranilic-acid tests	Takata-Ara tests									
	Negative (56)			Positive (64)						
	-	(-)	±	(+)	+	++	+++	++++	+++++	
Negative (67)	-	31	3	2	7	7	1	4
	(-)	1	3	1	1	1	1	..
	±	..	1	1	1	1	..
Positive (53)	(+)	4	2	2	3	8	1	3	1	..
	+	..	2	2	..	1	3	1	2	1
	++	1	3	5
	+++	3	1	1
	++++
	+++++	1	2

Agreement was found in 86(83) samples (71.7(69.2) %). Agreement was complete in 49 samples, good in 27(24) samples, and fairly good in 10 samples. Discrepancy was found in 34(37) samples (28.3(30.8) %). Positive Takata-Ara and negative chloranilic-acid test in 23(24). Negative Takata-Ara and positive chloranilic-acid test in 11(13). * Diagnoses: acute hepatitis (6 cases); hepatitis (2); hepatic cirrhosis (6 cases + 1 doubtful case of alcoholic cirrhosis); cholelithiasis (1); cholangitis or cholecystitis (?) (1); hepatic cyst (1); cancer of pancreas with metastases (1); heart-disease and lterus (1); leukaemia (1); sarcomatosis (1); mammary cancer (Op.). carcinomatosis (1); pulmonary tuberculosis (1); and proteinuria (1).

two series is clearly too small to be of any significance for the outcome of the reaction.

That the present test may be as useful as the Takata-Ara test in the diagnosis of severe liver damage is clearly shown by the excellent agreement between the results obtained by the two tests.

From Oct. 15, 1951, to Oct. 15, 1952, 650 blood samples were tested by both the chloranilic-acid and the Takata-Ara methods. In only 37 samples (5.8%) were dissimilar results obtained—i.e., the chloranilic-acid test gave 15 "false" positives and was negative in 21 samples which gave a positive Takata-Ara reaction.

All the 120 results recorded in the 25 patients from which the 37 samples mentioned were derived are shown in table III. They show that the two methods agree well on the whole but occasionally give discordant results, in some cases rather striking.

Since Jan. 15, 1953, the new method has been used as our routine method at the Aker Hospital, 1064 samples of blood being tested thereby up to Jan. 15, 1954. In 26 cases a Takata-Ara test was also made; in 3 of these cases a positive Takata-Ara was associated with a negative chloranilic-acid test.

The Takata-Ara test was usually made in cases where the clinicians threw doubt on the result of the chloranilic-acid test, especially where they thought that a negative result did not harmonise with the clinical picture. This may explain the higher degree of discrepancy (11.5%) between the two methods in this small series.

It may be inferred that the chloranilic-acid and Takata-Ara tests seem to be related in so far as they both reveal grosser changes in the proteins and thus may be regarded as approximate measures of the severity of the liver damage.

The test described here has, however, the advantage that it is much easier to make, because only a single tube is needed for each sample of blood, and the result can be obtained within half an hour if the mixture is centrifuged.

Summary

A new liver-function test (with chloranilic acid) is described.

The chloranilic-acid reagent gives voluminous precipitates in normal sera, whereas the precipitate formed in sera from cases of parenchymatous liver disease decreases with increasing severity of the liver damage. In the worst cases no precipitate is formed.

Like the Takata-Ara test the chloranilic-acid test detects grosser changes in the serum-proteins accompanying the more severe degrees of liver damage.

The test is easier and less laborious to make than the Takata-Ara test, and the result may be obtained within half an hour, provided the readings are made after centrifugation.

Preliminary Communication

SIGNIFICANCE OF ASCORBIC ACID IN THE ADRENAL CORTEX

THE significance of the high concentration of ascorbic acid in the adrenal glands, anterior pituitary, and corpus luteum is still obscure. Its rapid disappearance from the adrenals of animals exposed to various kinds of stress has not been satisfactorily explained, although the degree of depletion has been used for quantitative biological assay of adrenocorticotrophic activity.¹ The simultaneous reduction in the cholesterol content of the gland has led to the belief that both these substances are concerned with the production of the cortical hormones.² A second suggestion was that ascorbic acid might in some way be incorporated to render the steroid hormones water-soluble.³ Vogt⁴ and Oesterling and Long,⁵ however, found no evidence to support either view. Recently, Dugal and Therien⁶ have stated that though ascorbic acid fails to replace corticotrophin (A.C.T.H.) in maintaining adrenal weight in hypophysectomised rats, the two substances seem to act synergistically in this respect when given together.

Hypophysectomy in the rat results within a few days in pronounced reduction of the adrenal weight.⁷ Histological sections of such glands show atrophy of the zone fasciculata and reticulosa, owing to a great reduction in their cell volume. The consequent crowding of the nuclei in these layers becomes very conspicuous. Such atrophic glands also lose their high degree of sensitivity to corticotrophin as judged by Sayer's ascorbic-acid-depletion method. The administration of corticotrophin as replacement therapy can prevent this atrophy, and has in fact been used as an alternative method of assaying adrenocorticotrophic activity (adrenal maintenance test).

The possibility that the high concentration of ascorbic acid in the adrenal glands might have a rôle in maintaining the adrenal weight was investigated in the following experiment. Twenty male albino rats, each weighing

about 100 g., were hypophysectomised and were divided into two equal groups. Each animal in the first group was given a daily intravenous injection of 100 mg. sodium ascorbate (Roche) in saline. Each animal in the second group was given the same volume of saline by intravenous injection. After a week all the animals were killed and their adrenals weighed immediately. A third group of ten intact animals of the same weight were also killed and their adrenals similarly weighed. The average weights of the glands in each of the three groups are shown in the accompanying table.

WEIGHTS OF FRESH ADRENAL GLANDS (MG. PER 100 G. BODY-WEIGHT)

Control rats	Hypophysectomised rats	
	Saline	Ascorbate
25.0 ± 1.2	12.2 ± 0.2	21.8 ± 1.3

These figures indicate that following hypophysectomy the reduction in adrenal weight, which would otherwise take place, can be almost averted by means of ascorbic acid only. The observed difference between the saline-treated group and the two others is statistically

Sections through adrenal cortex, fixed in formol saline and stained with Sudan III. (a) Intact control. (b) Hypophysectomised treated with saline. (c) Hypophysectomised treated with sodium ascorbate. ($\times 110$.)

significant; that between the control and ascorbate groups is barely significant ($P = 0.05$).

Frozen sections of such glands are shown in the accompanying figure. It appears that the adrenals of hypophysectomised rats treated with ascorbic acid contain much less cholesterol than the adrenals of the other two groups. Further work is in progress to find out whether ascorbic acid has any potentiating effect on the adrenal weight-increase or adrenal weight-maintenance produced by corticotrophin in hypophysectomised rats.

ROYAL SOCIETY OF MEDICINE

Effects of Antibiotics

THE section of comparative medicine met on April 21, with Prof. T. J. BOSWORTH, the president, in the chair, to discuss the Effects of Antibiotics on the Host.

Prof. L. P. GARROD said that the ideal antibiotic would not harm the host at all; but of the many antibiotics which had been discovered only a very few had stood the test of time, because in one way or another they could be more harmful than beneficial to the host.

Five types of effect on the host could be recognised: toxicity, sensitisation, vitamin deprivation, super-infection, and growth promotion.

Toxicity.—Of all the antibiotics penicillin was by far the least toxic—astonishingly high concentrations of penicillin (even up to more than a thousand units per ml.) could be achieved in the blood without ill effect. One of the great dangers with streptomycin was the production of deafness, which might be permanent. The toxic effects of chloramphenicol on the bone-marrow had caused much discussion, and excessive doses of aureomycin and oxytetracycline (terramycin) were known to harm the liver. Polymyxin and bacitracin, particularly the latter, were apt to attack the kidney. Professor Garrod pointed out that his experience of these toxic effects was mainly in man. The effects in animals might be different; some effects in animals might also be more difficult to detect—for example, deafness in a cow.

Several antibiotics had been found to cause *sensitisation*. Some 20 cases of sudden death following administration of penicillin had been reported. These cases were thought to be anaphylactic; they apparently occurred always in persons who had had a previous injection, especially when procaine penicillin had been used. Penicillin and streptomycin were both commonly the cause of skin rashes, especially in nurses who were frequently handling the drugs, or when these antibiotics were applied repeatedly to the skin. Here again it was not so easy to say what happened in animals, in which some types of hypersensitivity reaction would be much more difficult to detect than in man.

Vitamin Deprivation after prolonged use of antibiotics had been described. This could be the result of suppressing the kinds of bacteria in the gut which contributed to the vitamin requirements of the host. Cases of this kind could not arise if vitamins were given with the antibiotic.

Super-infection was a serious problem and could take many forms. For example, a pneumococcal infection might respond to an antibiotic such as penicillin only to be replaced by a *hæmophilus* infection which failed to respond. The use of the "broad spectrum" antibiotics was sometimes followed by staphylococcal or candida infections of the air-passages or bowel: staphylococcal enteritis might be fatal. The mechanism of this type of catastrophe was at present obscure.

Growth Promotion.—This was one of the most interesting effects of antibiotics on the host. Professor Garrod would leave it to other speakers who were actively working in this fascinating field to say more about it.

Prof. ALAN KEKWICK discussed certain aspects of the pharmacology of penicillin, streptomycin, chloramphenicol, aureomycin, and oxytetracycline. Despite the very great volume of work that had been done, there were still enormous gaps in our knowledge of the optimum dosage of these drugs, in relation to route and frequency of administration, ease of absorption, excretion, toxicity,

and so on. Often an adequate clinical response might be obtained with doses far lower than those customarily used; these usual doses sometimes approached the maximum which could be tolerated, though the tolerance might vary greatly between different species of animal.

Mr. W. S. GORDON, PH.D., after describing briefly the discovery of the growth-promoting effects of antibiotics, gave an account of the work which he and his colleagues have been doing in recent years in an attempt to find the mechanism responsible for this feature. Its occurrence was well established in many species of animals—including young children—and even in young plants as well. Increases in growth-rate of the order of 10–15% in treated over controls had been recorded, together with an improvement in food conversion, which resulted in more rapid fattening of pigs and poultry for human food with consequent increase in profit to the producer. Of equal, if not greater, importance, however, was the apparent reduction in clinical and subclinical infections which retarded growth.

Certain experiments gave a clue to the probable explanation. For example, the addition of antibiotics to the "germ-free" chick embryo did not stimulate growth, whereas after hatching a growth response could be elicited. The fundamental study of "germ-free" life by Professor Reyniers at the Lobund Institute of Nôtre Dame University clearly showed that "germ-free" animals derived no benefit from an antibiotic supplement, but would grow as fast as conventional, or bacteriologically contaminated, animals receiving such a supplement. The growth stimulation appeared to occur only in conditions where the environment had been contaminated by previous populations of the same species, and if the antibacterial properties of an antibiotic were removed it no longer appeared to possess the ability to stimulate growth. Even with concentrations of penicillin or aureomycin as low as 4 parts per million in the diet (approximately 0.13 mg. per kg. body-weight) antibiotic was detectable in the small intestine, stomach, and urine in the case of penicillin, and throughout the digestive tract with aureomycin. With concentrations of 128 parts per million in the diet (approximately 4.2 mg. per kg. body-weight), detectable levels in the serum were obtained with both antibiotics.

Mr. S. K. KON, D.S.C., described experiments indicating that the effect of antibiotics on growth is related to environmental conditions. When a few years ago tests with antibiotics were begun at the National Institute for Research in Dairying, where chicks had been kept for a long time, positive results were consistently obtained; but workers at the Glaxo Laboratories found at the same time no response. Joint work showed that under otherwise identical conditions antibiotics were ineffective where chicks had not been kept before but improved growth in long-used premises. In these the antibiotics acted not so much by promoting growth as by removing a growth-depressing effect attributed to an inapparent "infection" in birds otherwise quite healthy by conventional standards. Further studies at the N.I.R.D. in isolation boxes showed that the "infection" could be transmitted by addition to the food of raw gut contents, but not of autoclaved ones of "infected" chicks or of those raw from "uninfected" birds. The gut weight of chicks responding to antibiotics was less than in the lighter controls. There was good indication that this effect on the gut was not direct but mediated by the microbial population since the gut-weight of "uninfected" chicks was not reduced by antibiotics. The nature of the "infection" was still obscure, and we had still much to learn both about the normal population of the gut of chicks and other animals and the effects on it of antibiotics.

Tonsils and Adenoids

The section of general practice met on April 21, with Dr. A. TALBOT ROGERS, the president, in the chair, to discuss the problem of Tonsils and Adenoids.

Dr. OLIVER PLOWRIGHT said that in children over 12-15 years old there was no problem: "If in doubt, take them out." The discussion was centred on younger children, and the two structures had to be considered independently. Sometimes the adenoids alone required operation, though not every surgeon could be persuaded of this. The indications for adenoidectomy were fairly straightforward; in the majority of cases there was either nasal obstruction, evinced by mouth-breathing with snoring in the absence of coryza, or recurrent otitis media or deafness. The mother's story, the child's breathing, and an indrawn fixed ear-drum on auriscopy usually led to the diagnosis. The indications for tonsillectomy were less universally agreed. Before the present century it was a rare operation; but recent surveys showed that at least a quarter of all children in England and Wales had been subjected to what the Medical Research Council termed "a routine prophylactic ritual" by the age of 14, and the proportion was higher in the United States. More than three-quarters of boys starting at Eton had had their tonsils out. Dr. Plowright thought that today repeated upper respiratory infections were commoner; in consequence tonsils were larger. Size was no index for operation, nor was persistent enlargement of the tonsillar lymph-gland; while chronic infection of the tonsil was difficult if not impossible to detect. He regarded the theory of focal sepsis as completely dead. Recurrent frequent tonsillitis with persistent lymph-glands, or one or two quinsies, pointed to the need for operation; but tonsillitis had to be distinguished from a plain sore throat, and recurrent colds suggested rather focusing attention on the adenoids, or better still on the conditions of overcrowding the child probably suffered at school and at home whence he drew his infections. The tonsils, after all, were there to protect the child, and should be preserved if possible. But it was often difficult to convince parents of this: unfortunately tonsillectomy had prestige in their eyes. Tonsillectomy was very rarely necessary for respiratory obstruction, or for treating the diphtheria carrier (when other methods had failed). A few children who had their tonsils and adenoids removed for no very good reason did proceed to grow and enjoy better health afterwards. But it was wise to be conservative: there were 85 deaths per annum from the operation; there were the psychological risks of night terrors and enuresis, to say nothing of sudden hæmorrhage or of the enhanced risk of bulbar paralysis in poliomyelitis.

Dr. WILFRID SHELDON agreed that tonsils and adenoids must be considered apart, and to Dr. Plowright's indications for adenoidectomy he added three diagnostic points. The first was that chronic sinus infection was commonly linked with enlarged adenoids. The second was that a child who was sick in the early mornings before breakfast, with a slimy vomit, had probably been swallowing mucopus all night, and needed attention to the adenoids; but neither of these associations was invariable and absolute. The third was a diagnostic warning. The child brought with a history of frequent absence from school because of colds, of much early morning sneezing, and of vigorous nose-blowing with very little result, was suffering from allergic rhinitis, for which operation on tonsils and adenoids was useless. Dr. Sheldon also advised caution in recommending tonsillectomy. Acute tonsillitis was a sign that the tonsil was functioning effectively as a trap for infection. Three attacks in a year meant nothing if the tonsils were healthy between them, and a source of infection in the household should rather be sought and treated. A tonsil was probably unhealthy, no matter its size, if there were congested vessels in the anterior faucial pillar, and if there were a granular pharynx and

persistent firm lymphatic glands at the angle of the jaw and in the anterior triangle of the neck. A child who failed to thrive, or lost its appetite, might benefit from tonsillectomy, while some cases of vomiting and of bad breath were cured by this operation. He also believed that focal sepsis was still a valid idea; and tonsillectomy might relieve, for instance, recurrent nephritic hæmaturia. This operation was valuable in the treatment of tuberculous glands in the neck, because the tonsil was usually the portal of entry of the tuberculosis. Tonsillectomy should be done whenever tonsillar disease impaired the child's health, no matter what his age.

Mr. R. J. CANN explained that while the tonsil could be removed completely by dissection or by the guillotine (much more difficult—a dying art) because it had a capsule and was visible, the adenoids had no capsule, were more concealed, and had to be scraped away; so it was physically impossible to remove them completely. When the tonsils were completely removed, particularly in the first five years of life, lymphoid tissue around the pharynx tended to hypertrophy as a substitute for regeneration. Thus rounded mounds swelled up on each side of the tongue base (lingual tonsils); the pharyngeal wall became speckled with plaques of lymphoid tissue; and a thick band of it developed behind the soft palate, particularly around and in the eustachian openings, where it tended to cause persistent middle-ear obstruction and deafness. Further removal was extremely difficult, but radium or deep X-ray therapy could be used. This tendency to hypertrophy or regeneration was a further reason for conservation rather than operation. In the nasopharynx the size of the lymphoid tissue created the trouble; whereas in the fauces it was infection which called for the operation, though the number of attacks per annum was not the guide. He thought continuing deafness was commoner than recurrent otitis, and eustachian obstruction commoner than nasal obstruction, in bringing the patient to operation. Tonsillectomy was avoided during epidemics of poliomyelitis, not because it increased the risk of catching the infection, but because it enhanced the likelihood of the disease taking the fatal bulbar form.

The subsequent discussion showed general agreement on the necessity for operating on tonsils and adenoids independently, and for avoiding operation altogether whenever possible.

MANCHESTER MEDICAL SOCIETY

Asthma Treated by Oral Cortisone

At a meeting of the section of medicine on April 7, Dr. WILLIAM BROCKBANK, with Dr. R. S. SAVIDGE, discussed the Treatment of Asthma with Oral Cortisone, on the basis of a blind trial on 24 patients severely incapacitated by asthma of long standing; their ages ranged from 17 to 70 years. 13 received regular maintenance doses of cortisone and 14 an indistinguishable control substance. 3 who were failures on the control were given cortisone. Of the 13 cortisone cases, 6 improved sufficiently to make a great difference in the ability to work and play; 4 more improved, but mostly subjectively; 1 was no better (this patient, who had severe emphysema, died eight months after the cortisone was discontinued); and 2 died while taking the drug. These results are very much better than in the control group; in 57% of this group there was no improvement, and 1 patient died. Side-effects of cortisone were few, increasing weight being the most important. The longest remission after withdrawal of the drug was eleven weeks. Most cases tended to relapse within a few days.

Cortisone cannot cure asthma, but some cases of long-standing chronic asthma can be effectively controlled by moderate doses of cortisone by mouth. But cortisone treatment is dangerous to life in some undefined types of asthma.

Reviews of Books

Peptic Ulcer

C. F. W. ILLINGWORTH, C.B.E., M.D., CH.M., F.R.C.S.E., F.R.F.P.S., regius professor of surgery, University of Glasgow. Edinburgh: E. & S. Livingstone. 1953. Pp. 287. 42s.

So much clinical and experimental research has been done on peptic ulcers that it is important from time to time to take stock of the facts and discard untenable hypotheses. Professor Illingworth does this with lucidity, simplicity, and elegance of language.

His own work on the incidence of ulcer in Glasgow enables him to condense the evidence as well as to indicate the fallacies in similar studies elsewhere and to emphasise the unexplained differences between peoples and places. In the section on gastric physiology he draws a clear distinction between speculation and fact that will be a great help to those who try to keep abreast of new work. The chapters on symptoms and treatment are outstanding, for here he writes with the intimate knowledge that only personal experience can give. The description and analysis of pain in peptic ulcer gives the reader a new comprehension of the experiences and reactions of an ulcer patient. Professor Illingworth's estimation of the value of the various methods of treatment, ranging from psychotherapy to surgery, is penetrating and practical.

The book is of modest size with well-selected graphs and illustrations and an extensive bibliography. It should be in the possession of everyone who deals with ulcer patients.

General Virology

S. E. LURIA, professor of bacteriology, University of Illinois. New York: John Wiley. London: Chapman & Hall. 1953. Pp. 427. 68s.

TEN years ago there were only one or two textbooks on viruses, but today nearly all self-respecting virologists have written or are writing one. Professor Luria's book is the first to treat virology as a separate branch of biology in its own right. His aim is to study plant, bacterial, and animal viruses as a group, despite uncertainty as to the extent of taxonomic kinship among what we call viruses.

He does not attempt to describe individual virus diseases or viruses; instead he deals with the facts and methods of virology as a whole. He first describes the techniques of virology and then the physical and chemical properties of virus particles in the resting state, and next considers virus-host interaction. Understandably, he gives most space to the bacterial viruses, since here the greatest advances have been made, many by himself and his colleagues. His experience with bacteriophages enables him to throw light on many important biological problems of animal and plant viruses, including variation, virus ecology, the relationship between viruses and tumours, and the origin and nature of viruses.

This book began as a course on viruses which Professor Luria gave to graduate and advanced undergraduate students at the University of Illinois. It has emerged as a collection of essays written with enthusiasm, imagination, and clarity, and it should appeal to mature as well as embryo virologists. Our respect for Professor Luria is only equalled by our respect for the intelligence of the students of the University of Illinois.

Medical and Scientific Investigations in the Christie Case

F. E. CAMPS, M.D., lecturer in forensic medicine, London Hospital Medical College. London: Medical Publications. 1953. Pp. 244. 30s.

Few criminal cases have enough medical and scientific interest to justify the compilation of a book of this part of the evidence; but like *R. v. Ruxton* and *R. v. Dobkin*, the case of *R. v. Christie* was full of problems: it was a job for a team—the forensic pathologist, the microscopist, the toxicologist, the mycologist, the anatomist, and the dental histologist, with ancillary radiology, plan and diagram drawing, and photography, not to speak of the C.I.D., and counsel and psychiatrist for each side.

Notable contributions to this book come from Professor Miles on the dental identity studies and from Richard Harrison on the ageing, sexing, and stature estimations (for assigning skeletal remains to missing victims). The former give further encouragement to the use of Gustafson's method of "points-value" ageing of individual teeth. But the dental experts do not seem to have read Thomas Bell's *Anatomy, Physiology, and Disease of the Teeth* (1829) which described pink teeth accurately—nor Tomes's later copying of this account. Had they done so their "considerable speculation" would have been averted.

The anatomical work provides strong support for the recent American stature estimation tables of Trotter and Gleser—undoubtedly less inclined to overestimate than Karl Pearson's famous regression figures—and there are good colour diagrams for reconstruction data by Peter Cull which must have made the jury's problem much easier. American criminal courts are taking more readily to the artist than ours in England, and the Attorney-General's authoritative use of these colour plans is welcome.

Just as we despair of accuracy in estimating the lapse of time since death (and these studies provided no help in this respect) so we are beginning to learn more of the longevity, after death, of the sperm in the vagina, and of the consequent insecurity of opinion on the date of intercourse. Contrary to general belief HbCO and myo HbCO are also long-lived: more bench-work on this problem would have improved Smith's chapter on CO absorption.

This is a painstaking account of the enormous amount of work that forged the medical and scientific links in the chain of evidence against Christie. A vast amount of useful observation and well-informed reasoning has been piled into the text, which is well illustrated and produced.

Resection-Reconstruction of the Hip

Arthroplasty with an Acrylic Prosthesis. JEAN JUDET, ROBERT JUDET, JEAN LAGRANGE, JEAN DUNOYER. Editor: K. I. NISSEN. Edinburgh: E. & S. Livingstone. 1954. Pp. 151. 30s.

THE Judet arthroplasty, as it is usually called over here, achieved immediate popularity because of the simplicity and directness of its conception, the relative ease of its execution, and the excellence of its early results as compared with any previous form of hip arthroplasty. Large numbers of patients were subjected to the operation even though no-one knew what the late results would prove to be. Though the gloomier prognostications of early critics have not proved correct, complications have nevertheless been sufficiently numerous to provoke a smart reaction; and now some maintain that the operation should be reserved for elderly lightweights who are never going to put any great strain on the new joint.

The Judet brothers and their co-authors have done 850 of these operations, and they claim some 80% of excellent or good results in their more recent cases, in which they have used their new prosthesis; but they are at pains to emphasise that patients have to be selected with great care. The appearance of an English edition of their book will be welcome to all orthopaedic surgeons in this country, and Mr. Nissen is to be congratulated on his editorship. The book is modestly written, and the difficulties and complications are described with an engaging frankness. Naturally, as the originators of the method, the Judets and their team have tried it in various conditions where there appeared reasonable hope of getting improvement—sometimes with disappointing results. Each type of disorder is discussed, and the chapter on late cases of congenital dislocation of the hip is particularly helpful, giving a clear picture of the limitations. The Judets use Hueter's approach as a routine, and believe that the exposure should be as limited as possible, so as to reduce interference with the blood-supply of the femoral neck. They obtained no better results with an extensive capsulectomy. In discussing the rationale of the operation in osteoarthritis they say: "the femoral head is the principal site of pathological change, and hence the main source of pain"—a conclusion with which not all would agree. They now do an acetabuloplasty more often than not.

Their results, good and bad, are given with obvious fairness, and they do not attempt to put the method

forward as a panacea. They have been responsible for a great step forward in the surgery of the hip-joint, and much honour is due to them. This well-illustrated book gives a worthy account of their stewardship.

Man's Ancestry

A Primer of Human Phylogeny. W. C. OSMAN HILL, M.D., F.R.S.E., prosector, Zoological Society of London. London: Heinemann Medical Books. 1954. Pp. 194. 21s.

Dr. Osman Hill has converted a short course of lectures to Edinburgh students of social anthropology into an excellent account of the probable path of evolution from the lowest forms of life to man. Naturally, he gives considerable space to the emergence of the primates, the rise of the anthropoids (the Australopithecinae are regarded as "essentially apes"), and the emergence of man. The various forms of fossil man and the chief prehistoric cultures, from palaeolithic to iron-age, are briefly described. He concludes that man is not descended from an anthropoid ape but from some more primitive animal:

"The hominid line, after emerging from the common Eocene pool of tarsioids, must have been represented by an unspecialised quadrupedal monkey-like Primate, possibly represented by *Parapithecus*. The line leading to the apes separated from that which gave rise to Man probably in the Oligocene."

The illustrations are good and an abundant bibliography, a glossary, and an index round off a useful work.

French's Index of Differential Diagnosis

(7th ed.) Editor: ARTHUR H. DOUTHWAITE, M.D., F.R.C.P., senior physician, Guy's Hospital, London. Bristol: John Wright & Sons. 1954. Pp. 1058. 5 guineas.

THIS edition appears after a ten-year interval under the new editorship of Dr. A. H. Douthwaite, who has collected a strong team of contributors, mainly from the teaching staff of Guy's Hospital and the Westminster Hospital. He has had the help particularly of Sir Adolphe Abrahams, whose many articles are models for publications such as this.

Dr. Douthwaite would be the first to acknowledge the magnitude of the task he has set himself—to cover medicine, surgery, and obstetrics and gynaecology in one diagnostic volume.

Many of the articles are admirable—clear, brief, and to the point. Some others are less effective, perhaps because for some symptoms—notably the neurological—there must be long lists of causes and classifications, and differential diagnosis cannot be set out in a short article.

It must have taken much hard work and great determination to complete this book without excessive repetition or overlapping. The index alone, on which a main purpose of this book must depend, covers nearly 150 pages and is a comprehensive and successful achievement. There are over 700 illustrations, many in colour, and high praise must go to the publishers for the printing and production.

Doctors will find the new "French" a practical help in their daily work, and they should be grateful to Dr. Douthwaite and his colleagues for their careful, thorough, and skilled revision of an old friend.

Medical Terms

Their Origin and Construction. FRANGCON ROBERTS, M.A., M.D., F.F.R. London: Heinemann Medical Books. 1954. Pp. 88. 6s.

THE curtailment of a liberal education through too early specialisation, which is the usual lot of the modern medical student, has prompted Dr. Roberts to explain to those who lack knowledge of Greek and Latin how medical terms have been constructed and how new ones should be formed. As our correspondence columns have lately shown, this is a subject in which many would like enlightenment, and Dr. Roberts is always a lucid and lively expositor. But his book is designed on an elementary level, and it unfortunately contains a good many small errors which will alienate the kind of reader who already has any considerable knowledge of words and may be correspondingly sensitive to inaccuracy in their employment. Thus, though the word "eponyms" is used correctly, the word "eponymous" is used

incorrectly to qualify the words instead of the persons who lend their names; "ballottement" is spelt wrongly; and the derivation of "anaphylaxis" is faulty, because Richet (who coined this word) preferred the meaningless "ana" as being more euphonious than the correct "a," meaning "without." Similar slips may be found every week in our own columns; but in a philological work they warn the reader that he is being addressed by a fellow doctor rather than a professional philologist.

Maxillo-Facial Laboratory Technique and Facial Prostheses

STANLEY BRASIER, chief technician, prosthetic laboratory, plastic surgery, burns, and jaw injury centre, St. Lawrence Hospital, Chepstow, Mon. London: Henry Kimpton. 1954. Pp. 230. 31s. 6d.

THIS is a good practical textbook for the trained dental technician who has no knowledge of the special procedures involved in making dental splints and non-dental prostheses. Plastic surgeons, too, may find it useful, for though in general they have not had enough technical training to be able to carry out the various laboratory techniques described, even if they wished to do so, they like to have a fair idea of what can be achieved with prostheses, as well as the limitations imposed by the materials available. There are a few statements with which both surgeons and dental surgeons may well disagree—e.g., "the edges of the ideal splint should extend into and beyond the gingival margin to a depth of about 2 mm." With all normal gingivæ this will rupture the periodontal ligament. Again, if connecting bars between sections of a splint are situated only 1 mm. from the mucosa, as suggested, the maintenance of good oral hygiene will be much more difficult than if these bars have a clearance of 5–6 mm. Minor criticisms such as these do not really detract from the value of this book, which should certainly be in the possession of all technicians undertaking maxillofacial laboratory work.

Peripheral Nerve Injuries (2nd ed. Philadelphia and London: W. B. Saunders. 1953. Pp. 333. 35s.).—Dr. Webb Haymaker and Prof. Barnes Woodhall note in the preface to this edition that in the Korean conflict peripheral nerve injuries have presented many diagnostic problems to medical officers not familiar with them; and it is to such officers, as well as to medical students and civilian doctors, that their book is directed. The first edition lacked an account of the pathological changes in injured nerves, but this omission has now been made good in a new chapter; and there have been many other changes and additions in response to suggestions and criticisms. The numerous illustrations, too, have been augmented by a further 47, and greater emphasis has been given to pain, trick movements, contracture, and electromyographic studies. It is a useful work.

Medical Register (London: General Medical Council. 1954. Two volumes. 65s.).—This year the Register contains 83,090 names of doctors (a decrease of 824 since 1953). The new registrations in 1953 totalled 507 (2390 below the average for the last ten years). These figures are at first sight astounding, but they are explained by the fact that provisional registration has come into force and accounts for another 1813 persons who have passed all their qualifying examinations. The Commonwealth list of new registrations, which jumped from 471 in 1951 to 1452 in 1952, fell back to normal at 436 (plus another 50 on the provisional register); and the list of new registrations of foreigners shrank to 7 (average for the past ten years 295).

Simple Craft Jewellery (2nd ed. London: Faber & Faber. 1954. Pp. 69. 8s. 6d.).—Under the auspices of the Worshipful Company of Goldsmiths of London, Mr. Claude Geoffroy-Dechaume has been responsible for the introduction of jewellery-making into hospitals, as a form of occupational therapy. Since the first edition of this book appeared he has arranged special courses of training for occupational therapists all over the country, and many hospitals have introduced this enjoyable little craft to their patients. One London hospital has even established a small anodising plant to serve its own makers of jewellery and those in other hospitals. A film has been made showing how the work is done, which serves as a supplement to this pleasant and well-illustrated book.

innocent fields?

... not to the sufferer from hay-fever! For him they may represent only the renewed discomfort caused by airborne pollen.

This widespread allergy, however, can be checked. In BENADRYL® there has been discovered one of the most potent of all antihistamines which provides effective relief for the vast majority of sufferers.

aureomycin

Lederle

shows
true economy

greater action...smaller dosage...lower cost

Now that the clinical value of Aureomycin in low dosage has been so universally confirmed, doctors and hospitals are finding that true economy can be effected when antibiotic therapy is called for. Aureomycin materially reduces the period of hospitalisation, disability and convalescence with a consequent substantial saving in time and cost.

Management of Coronary Thrombosis

IN recent years preoccupation with the use of anti-coagulants has perhaps tended to obscure other issues in the treatment of coronary thrombosis. WRIGHT et al.¹ and TULLOCH and GILCHRIST² have stated dogmatically that anticoagulants should be administered in all cases of cardiac infarction, and nearly all clinicians would agree that they should be given in cases of severe infarction accompanied by hypotension, circulatory insufficiency, prolonged pain, arrhythmia, or uræmia. Furthermore, anticoagulants may avert impending infarction in patients with progressively severe attacks of anginal pain occurring at rest as well as on effort.³ On the other hand, there is a growing weight of opinion in favour of withholding anticoagulants from patients who have had a clinically mild infarction without prolonged pain, circulatory failure, arrhythmia, or much fever. RUSSEK and ZOHMAN⁴ divided a group of cases untreated with anticoagulants into "good risks" and "bad risks," according to criteria similar to those already mentioned. The mortality was 60% in the "bad risk" group but only 1% in the "good risk" cases, while the incidence of thrombo-embolism was 10.6% in the former and only 0.8% in the latter group, although no anticoagulants had been given to either. LITTMANN⁵ reported 112 "good risk" cases, not treated with anticoagulants, in which there were 5 deaths, none of which was found at necropsy to be due to thrombo-embolism. Pulmonary embolism occurred in 6 additional patients, of whom 4 were having anticoagulants and 2 were not. FELDMAN⁶ found no difference in the mortality (30%) between 76 patients with myocardial infarction who had been treated with anticoagulants and 76 who had not. Although the difficulty of predicting which "good risk" cases will become "bad risks" within a few hours does suggest that anticoagulants should always be given, the risks and problems of anticoagulant therapy and the excellent immediate prognosis in most mild cases may persuade some physicians to restrict anticoagulant therapy to cases of severe infarction and to those with coronary insufficiency and threatened infarction.

The treatment of myocardial infarction does not begin and end with anticoagulants. Much remains to be learnt about the hæmodynamics and management of the acute phase in severe cases. CONNER and HOLT⁷ and PARKINSON and BEDFORD⁸ pointed out that in patients with shock and severe and continuing pain the immediate prognosis was grave, and sustained hypotension is clearly a source of danger. SELZER⁹ found this complication in 69 of 528 unselected cases of myocardial infarction, and noted that the mortality-rate was more than double that of patients without shock. He divided hypoten-

sion in his cases into four categories: immediate and brief; immediate and irreversible; coinciding with, and apparently due to, cardiac arrhythmias; and delayed, associated with congestive failure, which was always fatal. Apparently two mechanisms are at work—peripheral vasomotor failure, and acute left ventricular failure—but whatever the contribution of each there can be little doubt that persistent hypotension, with resulting inadequacy of the coronary circulation, materially lessens the chances of recovery. Detailed hæmodynamic data in the acute stage would be of great value, but are very difficult to obtain. The physician, moreover, is in some difficulty in choosing therapy, being poised between the Scylla of overloading the heart by treating the peripheral failure with intravenous fluids, and the Charybdis of losing his patient as a result of prolonged hypotension. Accordingly the treatment in this stage has hitherto been based on the well-tried combination of morphine, oxygen, and intravenous aminophylline if signs of pulmonary congestion are present. Adrenaline is contra-indicated in view of its action in increasing cardiac irritability, and the danger of inducing ventricular fibrillation. More active treatment has been advocated. SCHWARTZ¹⁰ and SAMPSON and SINGER¹¹ gave blood and plasma transfusions, without striking results. The use of pressor amines was suggested by BROFMAN et al.¹²; and *l*-noradrenaline, which does not increase cardiac output, and is said to increase coronary-artery flow,¹³ has been given to relieve hypotension¹⁴⁻¹⁶: 4 mg. of *l*-noradrenaline bitartrate monohydrate ('Levophed') is dissolved in 1 litre of 5% glucose, and administered by slow intravenous drip at a rate that maintains the systolic blood-pressure at about 100 mm. Hg. SHIRLEY SMITH and GUZ¹⁶ commented favourably on this method, while SAMPSON and ZIPSER¹⁴ reported recovery of 20 out of 30 cases with severe hypotension in which *l*-noradrenaline was given. Although the value of this form of therapy has still to be proved, it seems well worth trying in cases with persistent hypotension, in which the prognosis is known to be very bad, despite the risk that it may cause serious arrhythmia. Digitalis, especially by the intravenous route, is held to be dangerous in view of the liability to ventricular fibrillation¹⁷; but if rapid auricular flutter or fibrillation develops, digitalis is essential to slow the ventricular rate.

When the patient is past the acute stage, further treatment consists in continuation of anticoagulants, bed rest, sedation, and a light, salt-free diet. The action of anticoagulants in preventing thrombosis in the calf and pelvic veins should be assisted by leg exercises, supervised if possible by a physiotherapist or nurse. Straining at stool should be avoided, and the bowels kept well open. The physical and mental stress associated with struggling upon a bedpan is more hazardous to the patient than the use of a bedside commode or transport to the lavatory on a portable

seat. Adequate sedation is important. LEVINE¹⁸ has suggested that, once the acute phase is over, patients often do better if allowed to sit in a chair rather than lie in bed; he remarks on the reduction in bowel and bladder troubles, and the improvement in morale. Some support for this view comes from COE,¹⁹ who measured the cardiac work in bed and in a chair, in 6 patients—3 without cardiac disease and 3 with degenerative heart-disease. In all 6 patients the cardiac work was appreciably less in the chair than in bed. The same is not necessarily true for patients who have recently sustained a severe infarction; and the "chair treatment," although widely used in America, has not become popular in this country. Complications such as congestive cardiac failure and arrhythmias will require treatment as they arise. Elderly patients tend to develop hypostatic infection at the bases of the lungs, and the signs of infection may be obscured by basal râles due to left ventricular failure and by the fever associated with the infarction; appropriate chemotherapy is thus of great importance. Many patients develop frequent ectopic beats, and these may be the precursor of auricular fibrillation, or, far more serious, of ventricular tachycardia. The incidence of these sequelæ may be reduced by the administration of prophylactic doses of quinidine (0.5–1 g. daily) or of procaine amide ('Pronestyl') (0.25 g. two to four times daily). In such doses these drugs have no hypotensive action, but in large dosage they may cause an undesirable fall in blood-pressure. After a major infarction patients should remain in bed for six weeks, after which six weeks' to three months' convalescence is usually needed. Every effort should be made to encourage the patient to return to as normal a life as is consistent with his cardiac condition, while avoiding undue sudden mental or physical stress.

The further prognosis is that of the ischæmic heart-disease, and is necessarily uncertain in the light of our present knowledge. That the outlook is not necessarily gloomy is shown by an analysis of 412 patients with myocardial infarction by MASTER and JAFFE,²⁰ who found that 40% recovered completely, and of these 83% returned to employment; only 3% died in under three years, while 40% survived for more than five years and 25% for more than ten years. COLE et al.²¹ studied 285 patients who had their first infarction between 1932 and 1942 and who survived the first two months: 60% survived for more than five years, 40% for more than ten years, and 10% for more than fifteen years. These workers emphasise that the prognosis worsens with each succeeding infarct, and also that the longer a patient survives after one infarct the better is the immediate prognosis after subsequent infarcts, presumably because of the development of collateral vessels. Recent work points to disordered lipid metabolism as the cause of atherosclerosis^{22 23}; but there is still no incontrovertible evidence that any form of low-fat diet is of value in preventing further attacks of coronary thrombosis, despite the observations of Fullerton et al.²⁴ that fat

ingestion influences coagulation. Moreover, Professor DUGUID, in his paper at the front of this issue, is somewhat sceptical of the relationship of coronary atherosclerosis (as opposed to simple fatty changes in the arteries) to disordered fat metabolism. Obesity, however, is known to exert a harmful influence in persons with degenerative cardiovascular disease,²⁵ and patients who are overweight should certainly be encouraged to reduce their weight.

While the uncertainties of prognosis must be made clear to the relatives, an attitude of optimism should be maintained towards the patient, who should be encouraged to regard himself, not as a hopeless invalid in fear of his life, but as a useful member of the community who, though obliged to live within the limits of his disability, can still earn his living.

Malaria and Milk

IN the last two years several scattered observations on different aspects of malaria have been explained in the light of the discovery that a milk diet has an antimalarial effect. The story begins with work by MAEGRAITH et al.,^{26 27} who were investigating what happened to *Plasmodium berghei* in rats if its supply of hæmoglobin were handicapped by feeding the animals on a diet poor in iron. For this purpose a milk diet was given, and it was found that the malaria parasite failed to develop. It was then found that the suppression of the malaria parasite had nothing to do with iron, but depended on some characteristic of milk. (Fresh cow's milk, dried cow's milk, and human milk were all effective.) This remarkable suppressive action of milk was confirmed in many different parts of the world and was shown to apply to other malaria parasites, such as *P. cynomolgi* and *P. knowlesi* in monkeys. The action was exerted only on the blood forms of the parasite and did not affect the pre-erythrocytic stages in the liver.²⁸

The story entered a new stage when HAWKING^{29 30} discovered that the suppressive action of milk was due to its deficiency in *p*-aminobenzoic acid, which was known to be a growth factor for many malaria parasites—especially *P. berghei* in rats and *P. knowlesi* in monkeys.³¹ *p*-Aminobenzoic acid is well known as the bacterial growth factor which is antagonised by sulphonamides. The body-fluids of animals and man usually contain very little of this substance (otherwise sulphonamides would not cure streptococcal and other infections); but it is present in many diets, and when ingested in the food the blood-level rises sufficiently for malaria parasites to grow; it is rapidly excreted or destroyed, so constant renewal is necessary. Cow's or human milk usually contains extremely little *p*-aminobenzoic acid (only about 1 part in 200 million), which is insufficient for the growth of malaria parasites in either rats or monkeys; but if even 1 mg. is added daily to the milk diet of a rhesus monkey, infection with *P. knowlesi* can follow its usual acute and fatal course.

Although a milk diet usually prevents infection of rats by *P. berghei* in a very striking manner, in certain animals this action is not manifested. Probably such rats contain in their intestine bacteria which can synthesise *p*-aminobenzoic acid and so maintain an appreciable level in the blood. Intestinal bacteria which synthesise many components of the vitamin-B complex are well known; but it is difficult to prove their presence except by procedures which themselves exert an antimalarial action. These exceptions to the antimalarial effect of a milk diet, although common in rats, have not been encountered in monkeys. The malaria parasite requires besides *p*-aminobenzoic acid many substances for growth—e.g., methionine and ascorbic acid. *p*-Aminobenzoic acid is outstanding because the parasite needs it but the host can flourish without it.

The recognition of *p*-aminobenzoic acid as a growth factor for malaria parasites explains many diverse observations. Thus it elucidates the antimalarial action of sulphonamides (since these antagonise *p*-aminobenzoic acid), and of proguanil and pyrimethamine which are known to be antagonists of folic acid (a complex derivative of *p*-aminobenzoic acid) and which resemble sulphonamides in many other ways. Secondly this observation links up with the extensive work of microbiologists in elucidating the rôle of *p*-aminobenzoic acid in cell metabolism. Briefly, in bacteria *p*-aminobenzoic acid is largely built up into folic acid or similar compounds; then these compounds (or perhaps the original acid) act as catalysts for various important synthetic reactions, including the formation of methionine from homocysteine and the synthesis of purine and pyrimidine rings. These substances are essential for the formation of nucleoprotein and so for the growth and multiplication of nuclei and cells. In the case of the malaria parasite there is morphological evidence for a relation between the supply of *p*-aminobenzoic acid and the division of the nucleus. By histochemical methods (e.g., Feulgen staining) it can be shown that the division of the parasite's nucleus to produce sixteen or more merozoites necessitates the formation of a great deal of new desoxyribonucleic acid. And it is just at this stage of the parasite's development that it succumbs and disintegrates under the antimalarial action of sulphonamides, proguanil, or pyrimethamine (each of which interferes with the use of *p*-aminobenzoic acid or folic acid).

Finally, these findings may have an important application to malaria in man. Although men and women rarely subsist on a milk diet, there is one important class of human beings who do—namely, babies. It has long been recognised that babies in regions of hyperendemic malaria do not contract the infection as early or as intensely as would be expected from the degree of their exposure to infected mosquitoes.³² Hitherto it has usually been supposed that this insusceptibility was due to immunity transmitted in utero from the mother; but it now seems quite possible that the insusceptibility may rather be due to the milk diet. Suckling rats whose mothers have been placed on a diet free of *p*-aminobenzoate have proved relatively insusceptible to infection by *P. berghei*, but become highly susceptible if this compound is administered to them or to their mothers (thus increasing the concentration in the milk).⁵ Similarly baby monkeys maintained on milk from the breast or from a bottle are insusceptible to infection

by *P. cynomolgi*, but they readily become infected if they or their mothers are given *p*-aminobenzoate. The human parasites, *P. vivax* and *P. falciparum*, are sensitive to sulphonamides, so they presumably require *p*-aminobenzoate for their growth. It would be easy to jump to the conclusion that babies in West Africa are protected against malaria during the early months of life because they are fed exclusively on breast-milk, and that they become susceptible only when their diet is supplemented by foods containing *p*-aminobenzoate, or if the bacteria in their own or their mother's intestine synthesise this substance. But careful observation will be needed to prove such a hypothesis.

Epidemiology in Population Control

"GENERALLY, it is to be foreseen, that the Population of a Kingdom (especially if it be not mowed down by wars) do not exceed, the Stocke of the Kingdom, which should maintaine them." Thus, FRANCIS BACON anticipated the gloomy predictions of THOMAS MALTHUS. Ever since the publication of his essay, that English clergyman has been a centre of vituperative controversy.¹ Yet his basic postulates were indubitable: "First, that food is necessary to the existence of man. Secondly, that the passion between the sexes is necessary and will remain nearly in its present state." He then stated: "Population, when unchecked, increases in a geometrical ratio. Subsistence increases only in an arithmetical ratio. A slight acquaintance with numbers will show the immensity of the first power in comparison with the second." The happiness and welfare of a country depends on a balance between needs and material resources; with unchecked increases in population, "sickly seasons, epidemics, pestilence, and plague, advance in terrific array, and sweep off their thousands and ten thousands;" while "gigantic inevitable famine stalks in the rear, and with one mighty blow, levels the population with the food of the world." This "Malthusian scarecrow" has been dismissed by optimistic nutritionists, but ORDWAY² classifies such optimists as Cornucopians who believe that earth, sea, and atmosphere can deliver to the ingenuity of man an unending, inexhaustible supply of raw materials. Certainly the intensive development of agricultural methods in the past hundred and fifty years, which has allowed our planet to support a population of 2400 million, gives solid basis for that optimism. But as ORDWAY points out, in the United States in the past fifty years the population has doubled, while the consumption of minerals has increased eightfold and of fuel thirteenfold. There can be no comforting guarantee that the development of new material resources will keep pace with the pressure of needs. Conservation, he believes, is now the proper course; and in their recent discussion of public health as a demographic influence, Prof. JOHN GORDON and his colleagues³ share this cautious approach. Stung, no doubt, by VOGT's acid comment that physicians have "set the stage for disaster, and like PILATE, wash their hands of the consequences"

(a thought which EVANG,⁴ as a doctor, has expressed in less astringent terms), they review the repercussions of public-health practice in furthering population increase and suggest ways and means for harmonising population size and food-supply.

Realistic appraisal is the first task of epidemiology—the diagnostic science of public health. If population pressure be regarded as a disease of a society, an epidemiological survey of present circumstances will show its geographical distribution. In fact, the Asian peoples present the most serious economic and public-health problem. Western curative and preventive medicine has increased the population potential by cutting death-rates in circumstances of high fertility. In India, for example, between 1921 and 1941, declining mortality allowed a population increase of 83 million. As long as present birth-rates continue, population increases will tend to outstrip food production, leaving a precarious balance between needs and resources. Emigration and colonisation of undeveloped territory has long been the result of such pressure; but we are now approaching the limits of territorial expansion and overcrowding. Where that alternative is not available, the results of population increase can be disastrous. In British Guiana, for example, an effective antimalarial campaign between 1945 and 1948 reduced the infant-mortality rate from 250 per 1000 to 67 per 1000, with the result that by 1948 only 1500 calories per head were available to the people of the country. In India the caloric intake per head fell from 1776 to 1570 between 1934 and 1951. Where, as in Japan, an island community has no outlet for expansion, the problem is particularly acute. Ireland, Puerto Rico, and Sicily exemplify the drive towards emigration fostered by failure to achieve a satisfactory ecological balance between food and mouths. Only the Western nations of the U.S.A., United Kingdom, Scandinavia, and France have attained a reasonable stability in population numbers. The reasons for these disparities between countries in their demographic trends may suggest useful courses of action. The success of measures to control mortality depends on the whole population acquiescing in their application. The control of fertility must likewise depend more on general measures than on the unconcerted action of individuals. Such measures must take into account the historical and cultural background of a nation. A long period of high mortality demands a compensatory high level of fertility; and even when the death-rate falls, national procreative habits persist. Religious scruples determine both the drive towards family limitation and the methods used. Again, methods designed for adoption throughout a country must be both practicable and widely acceptable. While drugs such as phosphorylated hesperidine may prevent the sperm entering the ovum, it is unlikely that many men or women could be persuaded to achieve continual sterility by taking a tablet three times a day every day of life. GORDON and his colleagues believe that the traditional methods of epidemiology must be applied. The first essential is to recognise impending ecological disequilibrium from a simultaneous rise in population numbers, fall in the

average available number of calories per person, rise in unemployment, and increase in political ferment. Measurement of severity is the second essential for intelligent control; this calls for a detailed analysis of fecundity and fertility and their relation to marital habits and population age structure. Finally a carefully planned and controlled field trial will be needed to assess the efficacy of any measure of population control designed for universal use in an overcrowded community. Only thus, GORDON believes, can we fulfil COBBETT's recipe for rural content—that "the labourer must have his belly full and be free from fear."

In all this GORDON and his associates betray a caution which is hardly typical of their country. "Americans," said Mr. ADLAI STEVENSON, "have always assumed subconsciously that all problems can be solved, that every story has a happy ending"; and a report from the Rockefeller Foundation and the Twentieth Century Fund⁵ certainly suggests that there is a technical answer to every problem of human population needs. Yet CROMWELL would have approved of GORDON's tempering blind faith with an informed caution in order to maintain man's control over his own ecological balance.

Annotations

SPREAD OF MYXOMATOSIS

LAST October myxomatosis appeared in Kent, and since then it has been recognised in some eighteen areas, mostly on the South Coast but extending north to East Suffolk. We still do not know how the disease reached us from France, and there is no apparent connection between the various epidemic foci here. Official attempts to limit the area of infection by rabbit-proof wire fencing were, as we said,⁶ almost certain to fail; and the report⁷ of an advisory committee of the Ministry of Agriculture shows that this policy was rapidly abandoned. Faced with the probability of widespread myxomatosis in which 90% of the country's 100 million wild rabbits may perish in the next two years the committee has tried to forecast the economic consequences of such an epizootic. The total income from the wild-rabbit meat and fur trades is about £15 million. This is roughly the same as the damage caused by rabbits to cereal crops alone; and when we add to this the damage to pasture, vegetable crops, and young trees and the cost of pest protection, then the loss caused by the depredations of rabbits is likely to be three or four times as much. Nine rabbits are said to eat as much as two sheep; and in South-East Australia, where four-fifths of the rabbits were killed by the disease, the increase in rural production was estimated at £50 million. There is already evidence, however, that in some areas of Australia the mortality-rate from myxomatosis has fallen considerably; and if, as seems likely, this continues the gains may be short-lived.

While nothing can usefully be done to arrest the natural spread of myxomatosis in wild rabbits in this country, the protection of tame-rabbits is important—among other reasons, because some 40,000 are used every year for diagnostic and research work. The only known prophylactic is a preparation of the living virus of Shope's fibroma, and this is now being studied at Weybridge. Some workers in France claim that this

vaccine has not come up to expectations, and clearly we need much more information. Meanwhile breeders should take all possible precautions against the introduction of infection, and mosquito-proof screening and insecticides must be used until we know how the disease is spread. At present we rely on the excellent Australian work to guide us about the epidemiology of the disease, but this may have little relevance to conditions here. The introduction of myxomatosis into this country provides the epidemiologist and ecologist with a unique opportunity not only to provide practical information but to study what may be, in effect, a field experiment on an enormous scale.

A YEAR'S WORK IN THE TROPICS

THE report for 1952 of the Institute for Medical Research at Kuala Lumpur¹ describes an impressive amount of work.

'Daraprim' (pyrimethamine) gave a disappointing cure-rate in the treatment of malaria caused by *Plasmodium falciparum*. There were 13 failures in 97 cases of acute infection; increasing the total dose to 0.3 g. in five days did not improve the rate and produced leucocytopenia. Proguanil in doses of 400 mg. daily for a week failed to cure most attacks due to *P. falciparum*. Laboratory workers are glad to hear that the small Malayan *Macacus irus* monkey can act as a reservoir of *P. knowlesi*. Some of these monkeys have been imported to European laboratories to restock with fresh strains the dwindling strains maintained in rhesus monkeys.

American workers based on Kuala Lumpur have completed their stay and have now described interesting observations on rickettsial immunology. Clinical scrub-typhus has a latent period of about ten days and burns itself out naturally within two weeks of infection. Smadel and his colleagues² have isolated *Rickettsia tsutsugamushi* from an axillary lymph-node fifteen months after a natural infection. Using chloramphenicol to control the disease, they inoculated volunteers intradermally with known doses of the Karp strain, and demonstrated that immunity to a homologous strain lasts several years but infection with a heterologous strain is possible within a few weeks of the initial infection.³ By starting to administer chloramphenicol on the seventh day after inoculation they produced in volunteers both a demonstrable rickettsæmia and a long-lasting immunity (shown by subsequent challenge doses) with little or no overt clinical typhus.⁴ This production of immunity by chemoprophylactic control of a pathogenic vaccine in vivo is of some theoretical interest; but as Smadel et al. point out, it is of limited practical value because of the difficulty of exact dosage and timing of vaccine and prophylaxis. In 1941 a similar procedure⁵ was tried in South Africa, when sulphonamide was given to subdue infections in cattle with the rickettsia of heartwater disease.

Filariologists in Malaya add some interesting findings on treatment of *Wuchereria malayi* with diethylcarbamazine ('Hetrazan'). Some physicians have stopped using this drug on account of the sharp febrile reaction and allergic skin manifestations to which it quickly gives rise. The reaction is thought to be due to the release of parasite protein after the death of the microfilaria, and anti-histamine drugs do not entirely eliminate it. The severity of the reaction does not necessarily depend on the number of circulating microfilaria, and the workers

in Malaya now report that it seems to be independent of the size of the initial dose. They also point out that once this reaction has subsided the dose can be increased up to fourfold without ill effect. They have given one dose daily, which they find adequate. Reappearance of the microfilaria in the blood is slow, taking place over a year or so. (It is commonly believed that hetrazan kills the microfilaria and damages the production of it without actually killing the adult worm.) Nevertheless the decimated microfilaræmia has the effect of controlling transmission through mosquitoes. When the 1st Battalion Fijian Regiment left Fiji all those whose blood showed *W. bancrofti* were treated with hetrazan: on arrival in Malaya only 43 out of 725 had microfilaræmia, and in these the numbers were very low. A similar epidemiological situation arises with the arrival of East African troops infected with *Shistosoma hamatobium*, and the entomologists are busy finding out whether this can be transmitted by any local fauna.

RENAL FAILURE COMPLICATING PEPTIC ULCER THERAPY

ALKALOSIS and renal dysfunction due to excessive intake of milk and absorbable alkali in the treatment of peptic ulcer was first described by Hardt and Rivers¹ over thirty years ago. Cope² reviewed the condition in 1936 and emphasised the importance of hypercalcaemia from high calcium intake. A patient who has had this treatment for many years begins to complain of weakness and lethargy with impaired mental efficiency and powers of concentration. This may progress to stupor or even to terminal uræmic coma. The urine, often increased in volume to three litres or more daily, is alkaline in reaction and usually contains small quantities of albumin and hyaline or granular casts. The levels of blood-urea and of bicarbonate, pH, and calcium in the serum are all increased.

The disorder was further defined by Burnett et al.³ in 1949, and Dufault and Tobias⁴ have now described four further cases. The patients in order to alleviate ulcer pain often insist on taking vast amounts of milk—in some cases a gallon daily. (In a striking example recorded by McQueen⁵ this almost amounted to an addiction, the patient continuing to take milk despite the warnings of his physician.) This amount of milk contains 5.6 g. of calcium, which is many times the calcium content of an ordinary diet. Some patients take considerable quantities of calcium carbonate as well. If renal function is normal, excess dietary calcium is excreted in the urine and significant hypercalcaemia does not develop.⁶ This hypercalcaemia in a constantly alkaline urine leads to the progressive deposition of calcium phosphate in the distal and collecting tubules and eventually to renal failure and uræmia. At this stage the calcium output cannot be maintained and there is increase of serum calcium and phosphate, often leading to widespread metastatic calcification. Corneal calcification is of especial diagnostic importance; it is readily recognised in early cases by use of the slit-lamp and later by naked-eye examination.

It has been shown that the intake over short periods of large quantities of alkali and milk does not impair renal function.⁷ In most of the reported cases a high intake has been continued for many years before renal failure developed. This may develop more rapidly if there is unrelated renal disease, or after temporary acute

renal failure associated with severe hæmatemesis or pyloric stenosis. Rapidly developing uræmia secondary to hypercalcæmia is known to occur in many other conditions, particularly hyperparathyroidism,⁸ multiple myelomatosis,⁹ calciferol intoxication,¹⁰ and sarcoidosis.¹¹

The early diagnosis of uræmia associated with hypercalcæmia is of paramount importance since the renal failure is potentially reversible. Determination of the serum-calcium is essential since reliance on the Sulkowitch reaction for hypercalcuria may be misleading when excess calcium is no longer being excreted. The avoidance of alkalis together with a low calcium diet may be all that is required in treatment, but in severe cases the use of calcium-chelating agents, particularly ethylene diamine tetra-acetic acid, may be of great value initially.¹² This compound does not reduce the serum-calcium level but converts a portion to a biologically inactive complex which is excreted more rapidly. Differential diagnosis may be difficult in a comatose patient incapable of giving a history. The hypercalcæmia of excessive milk intake and of calciferol intoxication will respond to conservative methods alone; that associated with some cases of myelomatosis and sarcoidosis has been shown to be corrected by corticotrophin or cortisone.^{13 14} Hyperparathyroidism will prove resistant to all measures other than surgical removal of the causative adenoma.

GRADUATE WIVES

EDUCATION is an expensive but enduring possession, and in their latest broadsheet¹⁵ P.E.P. consider whether we are making the best possible use of married women graduates. Each year 4000 women graduate from our universities, and in due course about three-quarters of them marry. What happens to them? During the years when they are bringing up their family their education—as distinct from any vocational training—is certainly being well used. But are we giving them the opportunity to use it in middle age by returning to work suitable to their qualifications? P.E.P. have looked at these questions against the background of facts supplied by a survey of married women graduates made by Mrs. Judith Hubback, M.A.

Mrs. Hubback's findings are based on the answers to a questionnaire sent out, in 1953, to 2000 married women who had taken their degree in and after 1930 at Oxford, Cambridge, London, Birmingham, Durham, Reading, Nottingham, the University College of Hull, the University of Wales, St. Andrews, and Aberdeen; and 1165 (58%) of them replied. An almost identical set of questions was answered by 420 married women of the same age-group, none of whom had been to a university: they were drawn from the sisters, relatives, and friends of those who filled in the first set of questions.

Of the graduates, only 1% said they would not, if they had their lives over again, go to a university at all; and almost three-quarters said that they would study the same subject or subjects over again. Of the non-graduates, only 52% were satisfied with the education they had received, and would do the same again. Just under two-thirds of the graduates, and a comparable proportion of the non-graduates, had planned a career for themselves (other than marriage), though the careers aimed at by the two groups were slightly different. In both groups, however, teaching was a common choice: 34% of the graduates and 14% of the non-graduates had planned to teach.

Marriage ended the planned career more often among non-graduates than graduates; and a larger proportion of non-graduates (79%, as against 64% of graduates) found housework to be a full-time occupation. The size of the families was much the same in the two groups, and both experienced much the same difficulty in getting domestic help. About half the women in each group enjoyed domesticity, and the rest either tolerated it or regarded it with mixed feelings. About 19% of the graduates and 9% of the non-graduates were doing paid full-time jobs, and 34% of the graduates and 11% of the non-graduates were doing part-time paid work. Many women seek work when their children are old enough to spare them. Of the 1165 women graduates questioned, nearly 500 plan to work at some chosen job in the future and a further 88 intend to do some work but have not yet decided what sort.

In summarising these findings the broadsheet does less than justice to the contribution made to the community by women graduates—"it is probably fair to say that the majority of the graduate wives covered by this sample were making no direct use of their academic qualifications"—for in fact more than half of them were doing full-time or part-time paid work likely to draw on their education. But the return we expect from education in this country cannot be assessed entirely in terms of paid work, and, as the broadsheet points out, "the indirect contribution which a trained mind and cultured outlook can make to family life and to the life of the nation generally is very great indeed." Education is never wasted, and least of all on those who have the task of civilising the next generation.

BRACKEN POISONING

BRACKEN poisoning occurs in horses and cattle, and it can be produced experimentally in sheep and rats. In horses the condition is known as "bracken staggers," since incoördination is a prominent sign. "Bracken staggers" is a manifestation of thiamine deficiency, caused by a thiaminase contained in bracken, and the condition can be cured by administration of thiamine.¹ In ruminant animals the signs of bracken poisoning are different.² Sheep or cattle receiving a diet that contains more than 40% of bracken may continue to thrive for some weeks. Then the animals lose appetite, have a raised body-temperature, pass blood with the faeces, which become soft and contain much mucus, and die within a few days. The disorder is not improved by thiamine injected or given by mouth; and it seems that bracken poisoning in such animals, unlike that in horses or rats, is not associated with thiamine deficiency. The level of pyruvate in the blood of affected animals increases little, and the level of thiamine in the tissues is only slightly reduced.³

Naftalin and Cushnie⁴ have described their hæmatological and necropsy findings in adult cattle and young calves that had died after being given bracken. The essential lesion is extensive bone-marrow damage, affecting the megakaryocytes, the primitive white cells, and the primitive red cells; thrombocytopenia and leucopenia result. Subsequently there are multiple hæmorrhages, and bacterial invasion of the blood-stream leads to a generalised non-specific bacteræmia. After the onset of bacteræmia hæmorrhage becomes more severe and leads to death. Though erythropoiesis is affected, the number of circulating red blood-cells is little reduced until the onset of severe hæmorrhage. Moon and McKeand⁵ have reported the hæmatological changes in sheep given bracken. Poisoning is indicated by a progressive fall in red cells and hæmoglobin, though leucopenia and thrombocytopenia are also found. The

difference from the blood picture in bracken-fed cattle may be due to the ability of sheep to tolerate bracken feeding for much longer periods. Red cells have an appreciably longer life than white cells, and probably cattle do not survive long enough for the changes in the bone-marrow to affect the red-cell count. Several groups of earlier workers⁶ reported similar hæmatological changes in cattle with bracken poisoning, but the cause of the bone-marrow lesions in ruminants is not yet known.

The ruminant differs from simple-stomached animals in that it depends for its nutrition largely on the metabolic activity of the micro-organisms in its rumen. These micro-organisms break down cellulosic material, assimilate nitrogen from the feed, and synthesise vitamins of the B complex and vitamin K. When the mixture of food particles and micro-organisms passes from the rumen into the abomasum, or true stomach, the bacterial cells are broken down and their contents become available for absorption through the normal digestive processes. Bracken poisoning in the ruminant may result from disturbance of normal microbial activity in the rumen leading to a deficiency in the animal of some nutrient necessary for the maintenance of normal bone-marrow function. Several groups of workers³⁻⁵ have excluded the possibility of this nutrient being one of the known vitamins of the B complex, vitamin K, or vitamin C; but, as Naftalin and Cushnie point out, the dysfunction may be caused by lack of some essential amino-acid or of some still unidentified vitamin. An alternative hypothesis is that bracken contains a factor (or causes the rumen organisms to produce one) with a toxic action on the bone-marrow. But so far the only noxious principle discovered in bracken is thiaminase, which probably plays no important part in the production of bracken poisoning in ruminants.

VECTORCARDIOGRAPHY

THE diagnostic reliability of the electrocardiogram is now so soundly established that it is easy to forget that the absolute limits of normal—particularly of the P-R interval, and of the width of the QRS and the QRST complexes—are still not exactly agreed. Variations due to age, posture, and perhaps race, in addition to those caused by instrumental distortion, faulty technique, and inaccurate measurement, constitute the chief difficulties in the way of establishing statistically acceptable criteria.⁷ The use of newer leads, although invaluable in diagnosis, has increased the problem. There are other theoretical objections to the present electrocardiogram: the standard and unipolar limb leads and the chest leads record electrical activity only in the frontal plane of the body, although the heart, being a three-dimensional structure in a volume conductor, has electrical forces in other planes. The study of these forces as spatial vectors was first undertaken by Mann in 1920 but made little progress because their determination from successive measurements of the electrocardiogram was tedious even when aided by optical devices, such as that of Shillingford and Bridgen.⁸

The conception, put forward by Wilson and his colleagues,⁹ of the ventricular gradient has helped both in understanding the electrocardiogram and in distinguishing changes in the T wave due to abnormalities of QRS from those due to local abnormalities of the myocardium. The gradient is a vectorial expression of the combined electrical forces producing the QRS and T waves. Its magnitude is calculated by planimetry from the

algebraic sum of the areas bounded by the QRS and T deflections and its direction determined by plotting measurements in any two standard leads on Einthoven's triangle or Bayley's triaxial reference system. Fundamentally it is a measure of the duration and magnitude of the electrical forces produced by lack of uniformity in the processes of excitation and repolarisation of the heart muscle. Ashman and his associates¹⁰ have worked out normal values for the ventricular gradient and have found them to vary within wide limits; but they have been able to establish constant spatial relationships between the direction of the gradient, the QRS vector, and the long anatomical axis of the heart, and have shown that the gradient lies posteriorly to the long axis and the QRS vector still farther behind. Unfortunately measurement of the ventricular gradient is difficult and too cumbersome to be really useful in practice.

The adaptation of the cathode-ray oscilloscope by Shelling and others in Germany, and by Wilson and Johnston,¹¹ has made it possible to record automatically the time-course of the cardiac vectors. In some ways the direct vectorcardiograph is a more sensitive instrument for studying the myocardium than the electrocardiograph, but it has considerable limitations—for example, in the study of temporal relationships such as the P-R, Q-T, and T-P intervals—while normal standards are hard to define. In addition, a standard reference frame has still to be agreed on. Some favour Wilson's equilateral tetrahedron with the Einthoven leads and Wilson's central terminal, recording in the frontal plane, supplemented in the sagittal plane by an electrode on the back; whereas others prefer more complicated frames, such as those proposed by Duchosal and other Continental workers. The Wilson frame is at least simple in practice and has the theoretical advantage of being based on the Einthoven triangle. The presentation of frontal and sagittal loops so that they can be viewed as a single spatial vectorcardiogram is not easy. Stereovectorcardiograms have been attempted in several ways, including double photography of model loops and the use of additional electrodes to define other planes, but they are unsatisfactory in practice. A special circuit with unequal resistances producing oblique-plane vectorcardiograms which can be viewed simultaneously on adjacent oscilloscopes has been devised by Burch et al.,¹² and seems more promising. In an attempt to overcome the spatial limitations of frontal-plane leads, Trethewie¹³ has proposed an interesting simplified electrocardiography. By placing an electrode on the manubriosternal junction and another at the xiphisternum, with two others at the same horizontal level in the left midaxillary line and at the back of the right chest near the midline of the back, he has been able to record three leads at right-angles to each other. These should detect electrical abnormalities of the heart in both horizontal and vertical directions of the frontal plane as well as in the sagittal plane. Satisfactory electrocardiograms have been obtained from cases of known heart-disease, but confirmation from larger numbers is needed. Variations in the normal values of the leads, especially of the T wave in the horizontal lead, require statistical study if the method is to be of more than theoretical interest.

It is unlikely that either vectorcardiography, which is still chiefly a research method, or Trethewie's simplified system will replace electrocardiography. In doubtful cases clinicians, probably rightly, rely on the case-history and on other methods of examination rather than on statistical criteria.

TREATMENT OF THE CHRONIC MENTAL PATIENT

J. A. R. BICKFORD
M.R.C.S., D.P.M.

CONSULTANT PSYCHIATRIST AND DEPUTY PHYSICIAN-SUPERINTENDENT, DE LA POLE HOSPITAL, WILLERBY, YORKS

If a layman were to visit the nearest mental hospital he would see patients who had been admitted ten, twenty, fifty years ago; and he would wonder at the poverty of the resources at the command of psychiatry, that these fellow citizens should have existed for so many years in such a state and yet be as far from being cured as they were on the day of their admission.

In the De la Pole Hospital there are some 450 men other than those in the admission ward and the convalescent ward, and 67 of these have been in the hospital for less than one year. The remainder have been in for periods shown below:

Number	Duration of Stay (in years) of 384 Patients							
	2-4	5-9	10-14	15-19	20-24	25-29	30-39	over 40
	63	87	46	63	37	38	29	21

Psychiatrists are no less intelligent than general physicians; and mental nurses are probably more efficient, and certainly much more humane, than nurses in other kinds of hospitals. Mental hospitals are ugly and uncomfortable, but so are many other general hospitals. Why should results be so bad?

There are many points to be considered. Each doctor in a mental hospital will have under his care hundreds instead of tens of patients. The total cost of a mental patient is not likely to be more than £5 a week, whereas the cost of a general patient will be usually more than £10, and of a sanatorium patient, or a patient in a maternity hospital, it will be nearer £12-15 a week. Out of this money, the sum set aside for medical care for each patient will be some £2 in a general hospital; in a mental hospital it is about 4s.

The patient who develops a mental illness would be shocked if he knew how little the community is prepared to spend on him. If he asked about it, he might be told that he would be fed and sheltered and all his physical needs would be looked after; but that once his nursing was paid for there would be hardly any money left to pay for medical attention. There is in fact a general if unspoken belief that the patient in a mental hospital has no need of a doctor, and that he must be glad to be kept alive. Even the procedure of being kept alive is not perfect; perhaps for tens of years he will go without touching solid food after 5 p.m. He will usually be clad in shapeless tweeds, sometimes many years older than himself. Often he will be unable to go out of doors because he will have no shoes. As he eats, so will he sleep and live—without any privacy, and often in the company of 50-100 others. Such fresh air as he gets will be in a courtyard about twice the size of a tennis-court, surrounded by high railings. He may well feel that he matters little to his fellows.

The psychiatrist who works in a mental hospital has to contend with all these conditions; yet it can be truly said that he fails to make the most of his opportunities. The sickness from which psychiatry suffers is fundamentally that of the whole community: things are always divided into opposites, the good and the bad, the quick and the dead, the sheep and the goats; and to these categories doctors (and psychiatrists in particular) add the acute and the chronic, the curable and the incurable.

All psychiatrists agree that no effort must be spared to cure the patient when he first falls sick. So he is admitted to a modern, well-furnished, and comfortable

ward; he is treated sympathetically and energetically, and conferences are held by the medical staff to ensure that he is treated by the most effective means available. If he fails to recover within some three to six months, his treatment changes; he is still treated with kindness and sympathy, but skill and energy are tacitly withdrawn. He becomes a chronic patient; and as the tempo of his illness changes so does that of his treatment. He is moved from the admission ward to the main building where he is kept physically healthy. Spontaneous remissions of his mental illness are often observed (though the mode of his care discourages their occurrence); yet when they do occur they are not always acted upon. The statutory documents are accurately and regularly completed during the tens of years which remain. Where will he live, and how will he live?

There will be no privacy, no curtains or carpets, no pictures on the walls—save possibly framed illustrations from the Christmas magazines of the last century. Some two or three times a year he will see his doctor; if he particularly requests it he will get special interviews, but they will all be short: he is very lucky if he has any form of medical care directly from his doctor for more than half an hour in each year. His doctor cannot help this: he has many other patients. If the doctor works in both the admission wards and the chronic wards he will spend half his time in the one, seeing some 30 patients, and the remaining half in the other looking after some 200 patients. Or he may spend his whole time looking after the 30 patients in the admission ward, while his unfortunate colleague will spend his whole time looking after 400-500 patients in the chronic wards.

Clearly the psychiatrist feels that the acute patient needs more of his very limited time than does the chronic patient. Is this contention true? I suggest that it is absolutely untrue. In the admission wards patients with acute illnesses treated by physical methods get better or fail to improve almost independently of any psychotherapy they are given. Those psychiatrists who work in the admission wards are those who dictate the policy of the hospital, and the admission wards are well favoured with doctors—to such an extent, indeed, that the patients are overburdened with medical attention. The psychiatrist no less than the patient appreciates the pleasant furniture and surroundings of the admission ward; it is agreeable to talk to patients who are well dressed and who can talk sensibly. The senior psychiatrist will not willingly surrender these pleasant things to work in the aesthetically unpleasing and culturally barren atmosphere of the chronic wards. In the admission wards he is always surrounded by a relatively large proportion of patients who are improving—patients who remit spontaneously, and patients who cannot help but get better on physical treatments. But between the admission wards and the chronic wards there is a gulf bridged only by the chronic patient.

The Chronic Patient

The facile distinction into "curable" and "incurable" patients is not confined to the administrative buildings of a hospital but is spread far around. Sometimes the hospital has a block of buildings for acute, recent, and eminently recoverable patients some miles away from the buildings used for the chronic patients. Sometimes a city will have a hospital or two for acute cases; patients who do not respond rapidly to treatment in these hospitals are discharged, and have to seek admission to another hospital which rarely admits cases of good prognosis. In it are usually found cases of organic intellectual deterioration, epilepsy, recurrent and chronic psychosis, and mental defect. Everywhere there are more doctors in the small hospitals than in the large overcrowded hospitals for chronic patients.

The rational treatment of psychotic illnesses is impossible unless their natural history is known; but very few psychiatrists have any conception of the natural course of these diseases. Schizophrenia will eventually remit: perhaps not for ten, perhaps not for fifty, years; but remit it will. The parole wards of mental hospitals are full of patients who have reached their remissions. They may still have some odd ideas, but they have learnt to live normally, and to avoid talking about their strange experiences or reacting to them. The possession of delusions is no reason why any patient should remain in hospital: what counts is the effect of the delusions on his behaviour. Patients with paranoid illnesses can be taught to live with their delusions unchanged but with their attitude so much modified that they need not be in hospital. Pathologically quarrelsome and difficult epileptics are often admitted to mental hospitals; but if they are handled with tact, kindly discipline, and encouragement they can be made fit to go home and live with their relations. The restless and violent senile patient rarely remains in this state for more than a week or two; after that he can easily be looked after, and the first step is to arrange for his admission to a geriatric unit.

Incarceration for the sake of incarceration is, of course, unknown; but spontaneous remission and adaptation are only rarely given an opportunity to develop. Yet praiseworthy efforts are made to make life in hospital pleasant for the chronic patient: occupational therapy classes, social clubs, frequent entertainments, games to watch and play, outside excursions in the summer, and instruction in painting and sculpture are all encouraged to some extent. These activities sound very impressive, and are ennobled by the name of "therapy"; but a visit to any occupational class will show this description to be false. The pattern is always the same: patients do, and continue to do, what they have some gift for doing. Patients make rugs who have done nothing else for years; women knit who would knit wherever they were: they would knit if the heavens were falling and the world crashing down around them. Painting is done by patients who have a gift for painting. There is nothing therapeutic in the overwhelming majority of occupational classes up and down the country. Occupational therapy has become an end in itself, the teachers and the taught indulge in activity which from the point of view of treatment is quite meaningless and absolutely useless.

Fitting Patients for Discharge

Psychiatrists who deal with chronic cases forget that the urgent need is to get patients out of hospital fit to work while they still have relations who are willing and able to look after them. The adolescent who develops an acute schizophrenic illness may remit in his late fifties; but by then he is unlikely to have fit and active parents, or even siblings, with a strong enough affection to look after him.

It should be made clear to patients when they enter hospital that they will not be allowed to stay indefinitely. The patient who leaves the admission ward for the chronic wards must be made to understand that his treatment has not finished, but rather that it has taken on the more obviously purposeful form of getting him fit to return to his home and work. A patient's relations will probably remain loyal to him and be prepared to look after him, even if he is not completely well, provided he is discharged within a year of his admission to hospital. If ten years have elapsed he may be completely well and yet be unable to leave hospital because he has no-one to befriend him.

The wards of a chronic hospital often contain 80-100 patients, and it is instructive to see how these patients pass their day. In the report book it may be stated that all but ten of them are working, either in or out of

the ward. In fact, some dozen patients will be out of the ward from 10 A.M. to NOON, and from 2 to 4 P.M.; 8 will go to occupational therapy classes, leaving 60-100 patients to clean and maintain the ward: and how they can all be usefully employed defeats reason. There are, in each ward, as many beds and chairs as there are patients; there are sufficient tables and a few leather sofas; there are lavatories, washbasins, and 4 baths; and there is the ward crockery. Surely it cannot take 60 or more patients all day to keep these objects tidy and clean—even though the curious importance attached to a well-polished floor consumes uselessly a considerable amount of time and labour. A patient is counted as "doing ward-work" if he carries a chair from one place to another at the direction of a nurse. No ward of this size could possibly take up the time and labour of more than a dozen patients, even if they took things very easily.

How then goes the rest of the day for the 60 patients who remain in the ward? They sit, or walk aimlessly about the airing-court or the ward; and do nothing else. Sometimes they are seen sitting tightly on benches against which a table has been pushed, because there seemed to be no other way of preventing them from fighting one another.

The annual reports of mental hospitals rightly stress the good work that is done, the new methods of treatment employed, the increasing number of cures, the provision of better recreational facilities and so on. Encouraging as it is to read these reports it would be even more encouraging if the hospital were to state the problems which have still to be solved and state them unmistakably in figures: reporting, for instance, how many patients have been kept in bed for disciplinary reasons; how many times disablement resettlement officers of the Ministry of Labour have failed to find work for patients who were fit for discharge; how many patients could not be discharged because there was no home for them to go to; how many were incontinent habitually; how many times the procedure for the follow-up of discharged patients has been inadequate, and how often this has led to the death of ex-patients.

An Experiment

In this hospital we are happy in that there has been for many years a liberal régime. Villas and open wards are available for about a third of the male patients; every day there is some form of entertainment; and parole outside the hospital grounds, as well as within, is readily granted. Despite these and many other good points the problem of the so-called dilapidated chronic patient has not been touched.

A patients' sports and social club did some good: an elderly man with an active delusional system, a most difficult patient, was transformed by this opportunity, and his good work for the club became well-known and widely appreciated throughout the hospital. He was willingly granted outside parole, and remains in hospital for no other reason than the lack of a home outside. An epileptic of poor intelligence, who for many years had been rightly regarded as one of the most dangerously aggressive patients responded to the same opportunities so well that he was granted first inside, then outside, parole and at last became a voluntary patient. When he left hospital he attended an industrial rehabilitation unit and was selected for a job.

Despite these measures the wards and their airing-courts were as full as ever of dilapidated patients, many of them regarded as actively homicidal and suicidal, many known to be incorrigible escapers for whom no control seemed effective except the one so readily adopted—confinement to the ward and all too often to bed.

The male side of the hospital was chosen for an experiment. The aim, it was agreed, should be to discharge all these apparently helpless patients in such a state that they would be fit to take and hold a job,

and live satisfactorily in lodgings or with their relations. Before a patient could be considered fit to do these things he must have proved himself fit to live in the hospital in a parole ward and to work in the hospital free from supervision.

The chronic wards were told to choose 6-12 patients for their hour-to-hour maintenance. Patients who worked usefully about the hospital or its grounds continued to do so. Every other patient was to be out of the ward in the morning and the afternoon. Apart from its dozen essential workers, then, each ward was emptied every morning and afternoon, and the patients were divided into groups, according to their age and physical fitness, and in these groups they worked or played. The fact that a patient was regarded as a persistent escaper, a homicidal or suicidal risk was taken as an absolute indication that he should be kept out of the wards and included in one or other of the groups.

Patients who were young and fit did what was essentially physical training, combined with games requiring thought. (Football, which tends to be purely mechanical pursuit, was forbidden except as a weekly game.) These patients trained together as a large group until they had learnt to do things as a well-coordinated unit; then they were divided into smaller groups wearing distinctive sports gear, so that each rank in the large unit was made up of different small groups. After a further period, each group worked on its own, always under the same nurse. Patients had to do things smartly and do them as a group. They were given things to do which they would enjoy doing, and which would provide them with thought as well as physical exercise, and everything they did had to have their active and their willing support. As they were seen to improve, individuals were put on a gardening squad, first under the care of a nurse and later under a gardener, and eventually they were given other jobs about the hospital or its grounds with the least possible supervision.

Older patients would sit about in the grounds, throw a light medicine-ball to one another, gather cut grass, or play cricket with a soft ball, never taking any strenuous exercise, or doing anything for so long that they became bored or physically overtired. They were encouraged to play bowls. Blind and infirm patients also left the wards and sat about or walked according to their physical abilities or their wishes.

There were some 20 patients who had all been in the hospital for many years and for whom no activity had ever been thought possible. Their behaviour was constantly violent and uncoöperative, and they suffered almost continuously from distressing hallucinations.

They were placed under the care of one nurse and given a large plot of rough ground. It was explained to the nurse that this ground belonged to the patients, and that it was his responsibility to turn it into a couple of tennis-courts, a bowling-green, and an ornamental garden. He was told that he could take as many years to do this as he found necessary, and that he would never be given any patients who were likely to be helpful or coöperative. The ground was rough, the grass stood high, and it was rank with stinging nettles and docks. His men were given forks and spades but no other equipment. The details of the work were left to him, and he was told he would be given no assistance or advice by the hospital gardeners. The work has gone well, the grass was burnt or torn up, the turf has been cut and stacked, the ground is being prepared. The Hospital Management Committee allow the patients to buy seed potatoes from them, and they buy back the crop; the patients will have the profits to buy fresh equipment.

The patients on this project, specially picked because they were difficult and uncoöperative, work very well and enjoy it. They resent wet days when they cannot go to their tasks. Once classed as "impossible" and "untrustworthy," they never make any attempt to run away, and they require only minimal supervision.

Nor is all this extravagant of nursing staff. No patients have been left in the wards except those whose

behaviour was very good; and their numbers were few so that ward nurses could readily be spared. Complete disuse of the airing-courts also released nurses; and in fact it was found that 180 patients could be well looked after by 8-10 nurses.

The whole of these activities were placed under the care of the hospital's good occupational therapy department. It was held that no patient should go to the occupational therapy department just because he was no trouble and worked well there. Patients can deteriorate as rapidly making rugs as they can while working with the hospital porters or just sitting in the wards doing nothing. We decided there must be a positive reason why they should indulge in any form of activity. The advantage of having the occupational therapist in charge of all these activities was that each separate activity remained a part of the whole and there were no separate kingdoms claiming allegiance from patients or demanding the allocation of additional nurses. A patient could easily be transferred from one unit to another as his progress dictated, still remaining under the same set of nurses.

On wet days, patients might give a ward an unusually good cleaning; and the recreational hall was used for some of the same sorts of activities as were carried on out of doors. With the coming of winter there had to be a change, though the improvement in the patients rather than the difference in the weather made it necessary. Other treatments were introduced. Young and active patients still continued to take physical exercise when possible, but in bad weather they were divided into groups of 12 who, with a nurse in charge, would sit and discuss the news of the day, read to one another, discuss their previous careers, or the places they had visited, read or write plays, listen to school broadcasts and discuss them, and so on. A group of deteriorated schizophrenics gave a very creditable concert. In the morning and afternoon the old men used one of the dayrooms in a villa as clubroom. Patients with gross organic brain damage, or a severe degree of mental deficiency, were given the job of constructing a cinder-path round the grounds, which will be useful to everybody because it is free from traffic. The emphasis, in this as in all other labouring activities, was on the therapeutic value to the patient of being employed usefully, and seeing that his work will benefit him and his fellows. No patient is kept at one job all the time; other ways of occupying him are introduced. The important thing is that the patient should see what he is doing and enjoy it; and no attempt is made to get the job finished in a given time.

Every effort is made to get patients home for the day, or the weekend, as soon as they show any sign of improvement. If there are no willing relatives, a nurse will take two or three patients into the city for an afternoon, and when a patient—who may not have been out of the hospital for twenty years—has improved enough, and gained enough confidence, he is encouraged to go on his own. If relations are willing to have him home but are not convinced that he is well enough, a nurse will accompany him on the first occasion.

We accept that view that all psychoses have an organic cause; and the usual physical methods are used where they are indicated. A doctor who looks after 400-500 patients can give psychotherapy only at a superficial level, but it is an essential adjunct to other methods of treatment. It is important for the patient to be able to accept his false beliefs and his disabilities, and yet to be able to refrain from acting upon them; for the habit of acting on them usually makes it impossible for him to live out in the community.

Every request a patient makes for a change of ward or for leave is carefully considered, and the fact that he has behaved badly in the past is not allowed to weigh

too heavily against him—indeed the historical approach to a patient is discouraged. The patient who was dangerous twenty years ago is only too apt to be still classified as a desperate homicidal risk.

When a patient is transferred to the main building from the admission ward, the reason for this is explained to him. He is told that the plan is to get him discharged soon, and every effort is made to win his coöperation. I have said that a patient does not have to be free from delusions to be fit to leave hospital; nor need his conduct necessarily be perfect under all circumstances: whose is it? A patient whose behaviour is impossible in one ward may behave perfectly in a parole ward, and be fit in every way to visit the city on his own, to seek work, obtain it and keep his situation.

Results

That this régime is successful needs no elaboration: the testimony of surprised and delighted relations and the great decrease in the amount of sedative drugs dispensed confirm this fact.

In the sick ward for older deteriorated patients, whose strength has declined with the years, many beds may be occupied by people who could, if they were encouraged, get up to go to the toilet, to eat, and to go out of doors when the weather permits. These patients tend to lie in bed, taking no interest in anything, constantly incontinent, and running a risk of developing contractures. In this hospital these patients are up and dressed and given simple occupational therapy—making paper bags for the canteen, sorting wool, and making rugs. Some who were formerly thought to be completely demented, and a permanent burden on the nurse, have become cheerful, more alert, and able in small ways to look after themselves and to get some enjoyment out of life and out of their families' visits. Within six months of starting this experiment there was not a male patient who was not receiving some form of active treatment every weekday.

Our revolution has been achieved without any increase in staff, without any patient being deprived of treatment which he needed because nurses were engaged with other tasks, and without the purchase of expensive equipment. Indeed it has been carried out without a penny's cost to the hospital. Confinement to bed is unnecessary, seclusion should never be employed, and it is rarely necessary to lock wards. Locked wards on the male side of this hospital are decreasing in number, and soon two-thirds of the male chronic patients will be in open wards. It is my belief that locked wards will eventually be dispensed with in all hospitals.

When the patient leaves hospital he will have to work; and he is therefore encouraged to work while he is in it. Meaningless tasks, such as hospital portering, are discouraged, and patients should never be allowed to continue doing them for more than a few weeks at a time without some pleasant and therapeutic activity being introduced as a break. A recoverable schizophrenic is not uncommonly discovered on the swill gang or on some other similar job where he will hardly ever see a doctor. Patients must have it explained to them time after time that they will one day leave hospital, and that they must prove themselves fit to start work and to lead a normal life by the time that day arrives.

Some Future Possibilities

If the opportunities were provided for patients to receive some pay for work when their stay was likely to be more than a few weeks, there are few who would not be fit to work and glad to do so. The problem of providing work for discharged patients could easily be solved, if industry would coöperate. Epileptics and chronic psychotics would be employed in a separate workshop, where they would not distress others by fits or strange behaviour.

Many patients require somewhere to live on, first leaving hospital: a hostel run by nurses and supervised by the hospital would be of great service to them. Moreover, patients who have been in hospital for a long time often find it impossible to get work. Their relations might be willing to have them at home if they were occupied; but the prospect of having them about the house all day and every day makes many refuse to have them at all. We arrange that discharged patients can attend at the hospital on all weekdays for occupational therapy, and have their midday meal there. They are allowed one day off, to attend at the labour exchange to look for work themselves. The same device is used for treating those not needing inpatient care, but requiring supervision and help.

For the success of such a plan as ours one thing is necessary: the willing coöperation of the nursing staff. Once this is gained much becomes possible.

Conclusion

Though psychiatrists and nurses are kind and humane people, treatment for any but recent admissions is generally almost non-existent in mental hospitals. Psychotics have an almost irresistible tendency to recover; but the process is checked because most psychiatrists are unaware of the natural course of psychotic illnesses. Moreover, the community is united in refusing to accept the psychotic when he has recovered from his illness even if he is an efficient and willing worker.

The psychiatrist can always be sure of the help of his nurses if he proposes to put into action a plan such as that described here. There are nurses everywhere—just as there are here—who will volunteer to look after a group of apparently irredeemable and degraded patients, and will eventually help these fellow citizens to regain a life which is pleasant and useful not only to themselves, but to their relations and to the community.

CANCER RESEARCH

THE 51st annual report of the Imperial Cancer Research Fund shows that its policy has not yet succumbed to the view¹ that cancer research should devote itself to chemotherapy and that the cancer problem can be solved only by retreating to basic sciences like genetics and biochemistry.

At the Fund's laboratories, L. M. Franks and P. C. Williams have studied the relation of oestrogens to prostatic cancer, using the hamster and guinea-pig for their experiments. It is now well known that a considerable proportion of old men show histological evidence of symptomless prostatic cancer and benign enlargement of the gland. Changes resembling human nodular hyperplasia or adenocarcinoma have only recently been reproduced in experimental animals: firstly, adenocarcinomas have been obtained by subcutaneous transplants of mouse prostate, together with hydrocarbon-carcinogens; and, secondly, local application of "the carcinogen" (presumably oestrogen) to ageing oestrogen-treated hamsters has induced acinar carcinoma of the prostate resembling that seen in man.

Williams has observed the effect of cross-breeding a strain (R111) of mouse liable to mammary cancer with the C₅₇ strain which has shown no tumours during six years' observation at the Funds' laboratories. The C₅₇ line shows a high vaginal responsiveness to oestrogen and there appears to be an inverse relation between oestrogen sensitivity and incidence of mammary cancer. The hybrids (C₅₇ x R111) show a higher incidence of mammary cancer than even the C₅₇H line, and their vaginal oestrogen sensitivity is nearly as great as that

1. Committee on Growth of the National Research Council: 6th Annual Report to American Cancer Society. July, 1950, to June, 1951. 1953.

of the C_{57} mice. The comment of the report is a little hard to understand: "The assumption of a causal significance is not supported by tests carried out on the Foulds hybrids ($C_{57} \times RIII$). (It may be that the theorists cannot bear to have their generalisations upset.)"

The theme of the day in cancer research—the lung-cancer/smoking relation—is being pursued by A. M. Begg. A single intranasal inoculation of benzpyrene in arachis oil induces oat-cell carcinoma in Simpson mice after 200 days. The report mysteriously adds that "Dr. Begg has also been carrying out tests in rats, mice and rabbits of substances which, because of their nature and use, must necessarily be subjected to adequate tests for absence of carcinogenic activity."

C. Le Q. Darcel and G. Negrini are investigating fowl leucosis by tests on the transmissibility of lymphomatosis and erythroblastosis, the viral transmission factors, and the cytology of the tumours. Because one type of tumour is transmitted by cell-free extracts, and therefore by a viral-type agent, while the other is not, analogy between the two diseases suggests that a viral factor cannot be excluded in the second case, but that it could be too labile or liberated in too small amount to be demonstrated by the techniques so far developed.

"Claims have been made by other workers to have demonstrated that cell-free extracts produce these tumours after a long latent period, but they also found that extracts of normal chick embryos have a similar activity. The active agents in these extracts therefore cannot be analogous to the erythroblastosis virus of the fowl since the virus can only be obtained from homologous tumours and not from normal tissues of apparently normal fowls."

James Craigie's technique of preserving tumour tissue has had some remarkable results: primary benzpyrene sarcomas, induced in C_3H mice, could still be grafted successfully after five years' storage at $-70^\circ C$.

B. D. Pullinger has continued her work on mammary cancer in RIII mice which develops without the operation of the milk factor. Ovariectomy in ageing mice did not increase the incidence or total number of benign or malignant growths, but "ovariectomy in breeders at 9 to 10 months old produced a 14-fold reduction in the numbers bearing benign growths." Of special interest is Pullinger's conclusion, derived from "the part played by oestrogenic stimulation in the evolution of spontaneous growths in the mouse breast," that "in the strain used the action of oestrogen was analogous to the action of a *promoting* factor on experimentally induced papillomata of the skin."

Experiments on surface X-radiation of the nipple area of the mouse have yielded 7 mammary carcinomas in 29 mice which lived longer than $11\frac{1}{2}$ months. The report says:

"It is highly improbable that any of these tumours were spontaneous, and none was associated with primary ovarian tumours. One striking change in the directly irradiated mammae was complete involution with atrophy and failure to respond to endogenous oestrogen. This appeared before there was any evidence that malignant tumour formation had started."

H. G. Crabtree has carried out experiments to test his suggestion that *p*-aminobenzoic acid may play a specific rôle in the induction of liver tumours in rats by certain azo dyestuffs. This suggestion sprang from his discovery that a series of non-carcinogenic azo compounds, all of which yielded *p*-aminobenzoic acid on metabolic breakdown, could significantly retard the rate of induction of liver tumours in rats by butter yellow or *o*-aminoazotoluene. An alternative interpretation assumes that the presence of additional azo compounds might retard the rate of metabolic rupture of the carcinogenic molecule by competing for the enzyme systems involved in this process. Crabtree has now prepared a similar series of

azo compounds which, on metabolic breakdown, yield the corresponding sulphonic acid—sulphanilamide—instead of *p*-aminobenzoic acid. Four out of five members of this series of sulphur-containing azo compounds, when fed to rats together with butter yellow, delayed the time of appearance of liver tumours, compared with that in animals receiving butter yellow alone, by about 6 to 7 weeks. Sulphanilamide itself also had a similar retarding action on the development of tumours by butter yellow. The one sulphur-containing azo compound which failed to protect was found to be itself a weak carcinogen.

EUROPEAN LEAGUE FOR MENTAL HYGIENE

At a conference of this body held in Rome from April 7 to 11 the main theme was the relation of mental health to public health—a subject that will also be discussed at the conference of the World Federation for Mental Health at Toronto in August.

In her presidential address, Dr. DORIS ODLUM (London) said that an important step towards mental health had been taken by establishing in many countries national associations for mental hygiene which could bring together representatives of every aspect of the life of the community. Yet in nearly every country a large proportion of the medical profession was among the opponents of the mental-health approach. Investigations (admittedly on a limited scale) suggested that, in England at any rate, some two-thirds of general practitioners either fail to recognise the neuroses and psychosomatic conditions or are so opposed to psychiatry that they never seek psychiatric help. There was great need for the better education of the public in the principles of mental health and in the great help that psychiatry can give to those who are mentally sick. A growing appreciation of the psychosomatic disorders was making it more obvious that mental and physical health cannot be separated; and "there is," said Dr. Odlum, "a tremendous demand on the part of the public for help and guidance in their personal problems."

Dr. J. R. REES (whose address was given in summary by his wife, Dr. Hemingway Rees) spoke of the need for partnership between mental health and public health. The World Federation for Mental Health (of which he is director) was composed of 50% professional associations and 50% mental-health societies coming from many countries. Part of its job was to encourage further research and better treatment; but we should never be able to provide treatment for all who need it, and the more important task was that of prophylaxis. The chief considerations included the upbringing of small children, the effects on small children of separation from their parents, and the effects of stress and anxiety leading to the development of psychosomatic illness. In all health education it was necessary to cooperate with colleagues whose primary concern had been with the prevention of physical disorders.

Dr. DONALD BUCKLE (regional officer for mental health of the European region of the World Health Organisation) said that the first task of education in this field was to bring the concepts of mental hygiene into the open. Without this change of outlook nothing could be effective. It was only because in some countries this educational change had already come about that we had seen the legislative changes which had created improvements in the treatment of the mentally sick.

Dr. ANDRÉ REPOND in his paper pointed out that it is very difficult for the principles of mental health to make headway against the deeply ingrained tendency of human beings to rely on magic, especially in relation to health. Those working in this field must not underestimate the unconscious emotional influences working against their efforts to develop human beings with well-integrated and harmoniously balanced personalities prepared to face and to accept reality.

Dr. P. SIVADON (France) said that after a long period of opposition and apathy in France there had recently been a considerable improvement in the official attitude towards mental-health concepts. Many of the ministries

now had psychiatric advisers who were called in for consultation and some even had psychiatrists permanently attached to them—e.g., the permanent commissions for health, for education, and even for housing. Prof. DE SANCTIS (Italy) described proposals by himself and Dr. Carlo Vetere, who was a public-health doctor, for furthering mental-health work in Italy. Dr. E. STENDEL (London) described investigations into the social significance of suicide and attempted suicide.

In the discussion, Prof. H. C. RÜMKE (Holland), president of the World Federation for Mental Health, said that we must beware of adopting the attitude of dictators in mental health and laying down the law. At present our knowledge of normal man was very limited, and had been obtained largely through the study of the abnormal. The time had now come when we could go out into the world and try to study, in company with our fellow men in every field, the workings of the mind and personalities of normal people. Thus we should hope to arrive at some real understanding of the factors concerned in producing mental health. Prof. HANS HOFF (Austria) replied that although it was true that there was much we did not know, we did in fact know a certain amount and could put it into action in certain fields. For example, we could advise mothers on the upbringing of their children, we could help young people with their emotional problems, and we could also give help and advice in relation to employment.

Medicine and the Law

Loss of an Eye

A CLAIM for £3000 damages against a former house-surgeon at Dundee Royal Infirmary was dismissed in the Court of Session by Lord Strachan,¹ although he found the doctor guilty of professional negligence.

The plaintiff was a girl who in March, 1951, at the age of 15 months, had fallen face downwards on a broken cup and injured her left eye. At hospital the house-surgeon found a laceration of the eyelid but failed to observe any injury of the eye itself and allowed the child to be taken home. When she was seen some weeks later by the family doctor the eye was found to be blind and it was afterwards removed lest sympathetic ophthalmia should affect its fellow.

The judge said that the expert evidence of seven eminent ophthalmologists had agreed that the defendant should have reported the case to a specialist. As to whether his neglect to do this had caused loss or injury to the child, his lordship held that, on the evidence, the doctor had established his defence that the condition of the eye was irreparable from the outset, and that no treatment could have made any difference.

Accidental Overdose of Insulin

At a recent inquest² at Sedgefield, co. Durham, the coroner recorded a verdict of accidental death on a woman who died after being given an injection of 5 ml. of insulin. The patient, who was under treatment for mental confusion, was being given 5 units of insulin daily. The sister in charge of the ward, who had been looking after the patient since her admission to hospital on Feb. 28, said she had instructed a nurse, who came on to the ward the previous day but who had had training in insulin treatment, to give the patient her usual 5 units of insulin on the morning of April 12. The nurse queried the dosage verbally and the sister, in evidence, said she thought "units" had been mentioned. The nurse stated in evidence that she had said "5 c.c.s.?" in an inquiring tone of voice, and the sister had replied "Yes." The patient was later found to be in coma and died despite attempts at resuscitation. The coroner said that he thought the sister stated the correct dose but that the nurse misheard her.

The Widdicombe File

XI. THE SAD TALE OF MRS. SMITH

The County Medical Officer of Health

DEAR DR. COBBLEIGH,

EVER since I settled in partnership here I have been meaning to ask if I might come to your office and introduce myself. Sir Daniel Whiddon showed me your letter about his farm and I was sorry I'd been so dilatory.

Since I qualified I've retained the impression that the public-health doctors are to be spoken to only in emergency or in protest, and district nurses and midwives are the only representatives of the service that I've actually met. But I'm beginning to realise that you and others provide my patients with services of which I'm still ignorant. And I'm wondering whether you can help me with my problem families.

I have about a dozen of them on my list, and they give me more trouble than all the rest put together.

This afternoon I've been visiting the Smiths, of no. 13 Downtown, who are in constant trouble with the diseases of dirt and ignorance. As a young and inexperienced doctor, with all my illusions still about me, I've tried to approach the family in the crusading spirit, as a challenge to preventive medicine and health education. But I've so far failed miserably and have for the moment retired, frustrated and fleabitten.

* * *

The central figure in the Smith drama is Mrs. Smith, known to her friends as Our Rita. She is 38 and has five children, a sixth on the way, and a seventh in the graveyard. She herself was one of a large family of kind and feckless parents, was fairly well fed but seldom washed, and grew up with little training or discipline other than the exasperated slap. She was educated at vast expense by the State, but her low intelligence and frequent absences from school prevented her from learning anything more advanced than to read the comics. After leaving school she drifted through various jobs in laundries and shops and eventually settled into quiet and unexciting employment sweeping out a large store. Here she learned from the other girls, who were kindly and rather brighter; following their ways she came under the magic spell of Hollywood and went to the Odeon twice a week, where she could enjoy luxurious surroundings and Romance in Glorious Technicolor for 1s. 3d. Following the example of the Stars, she took up Glamour in a big way, smartened herself up, used make-up, and was more or less clean. With some decent clothes, uplift, and a perm she fancied she might become a star herself if a talent scout happened to come her way, but somehow one never did. For the most part Hollywood was quite a good influence on Our Rita, although as she came to spend more time and money on her appearance than on food, she became poorly nourished and underweight.

At the age of 18, it seems, she met Bill Smith, a steady-going chap who worked for the council, digging holes in the road; as a result of some rather disappointing physiological experiments in a hayfield it became expedient for her to become Mrs. Smith, which was not so romantic as she had been led to expect. However, the baby which arrived six months after they were married left her little time to worry about that. After living with her in-laws for a while they were lucky enough to get a council house on a new estate. To begin with, Mrs. Smith was proud of her new house and tried to keep it nice, but as she had never learnt much about housekeeping and cooking she found this difficult. The baby was a great worry to her, and the unaccustomed responsibility and disturbed nights made her tired and irritable. She had ceased to care about her personal appearance soon after marrying Mr. Smith. When the second baby arrived, eighteen months after the first,

she had far too much to do and things got on top of her ; the house became dirty and the cooking neglected. By a slow but unrelenting process of decay, accelerated by each childbirth, the Smith family became slum-dwellers.

It is easy for the stranger to pick out the Smith house. Most of the council houses in Downtown are well kept, with cheerful curtains in the windows and productive gardens. The garden of no. 13 contains a wilderness of weeds and a derelict perambulator ; the gate is loose on its hinges, there are no curtains in the windows, and the washing on the line is dirty. On entering the door the visitor is assailed by a strong smell ; there is a general appearance of dilapidation, and the floor and walls are dirty. What furniture there is, is falling apart, and the rooms are cluttered with dirty clothes and rubbish.

Mrs. Smith wears some ancient garments, which I can't describe and hope not to have to take off some day to examine her. She is anæmic, her teeth are bad, and she looks about 50, though she is only 38. She suffers from menorrhagia and abdominal pain, largely the result of coitus interruptus, and her varicose veins get worse with each pregnancy. She is by nature kindly, feckless, and uncomplaining. There are five children—Alf, Ern, Linda, Georgie, and Doreen—a sixth died of diarrhoea in infancy. They have runny noses and one or other of them is usually on my visiting-list for discharging ears, impetigo, or diarrhoea. They are dirty and their clothes are ragged, though adequate to keep out the cold. They are usually shod in rubber boots or canvas shoes ; they become noticeably cleaner when they go to school and find themselves laughed at by the other children for being dirty.

They look surprisingly robust, though their diet is predominantly carbohydrate, with potatoes, cream buns, ice-creams, and chocolate high on the list ; protein is supplied by school meals, the fish-and-chip shop, and a few eggs which the chickens in the back-yard sometimes produce. Mr. Smith provides £7 a week, is affectionate to the children, and believes in keeping out of the way as much as possible. About £4 a week and the children's allowance go to the house-keeping, the rest to beer, cigarettes, and the television set on the hire purchase.

* * *

That is the Smith family, resigned, dirty, but struggling along as best they can. They are good-humoured, generous, and in spite of everything likeable. The sordid state they live in is not due primarily to poverty, nor to housing difficulties, nor to lack of schooling, but to the unalterable fact that Mrs. Smith is of very limited intelligence and unteachable by ordinary methods. She is, in fact, a high-grade mental defective ; and it's on her inability to learn that all efforts at preventive medicine come to grief. With considerable persistence she can be shown how to keep the house clean and the children cared for, but in a few weeks the family is back again in squalor, the new baby and the toddlers being fed milk out of an old beer-bottle with a rubber teat stuck on the top of it.

The health visitor, the district midwife, and the general practitioner share the task of trying to keep the Smiths out of trouble. I think the health visitor plays the biggest part ; she has the special training in nursing and social work and can help Mrs. Smith over the shopping and the children's clothes. She understands the Smiths and is liked by them, so that she can keep up the pressure of benevolent nagging without offending them. I have met the health visitor in Widdicombe and discussed the problem families of the practice, to my great advantage. The district midwife is also on good terms with the family and helps them spring-clean the house before each new baby arrives. As the G.P. I have tried to show Mrs. Smith how to kill the flies with a D.D.T. spray and have given her ferrous sulphate tablets which she does not take. The most pressing need is to stop Mrs. Smith having any more babies, which would

give her a chance to look after those she has already. I have fitted her with a dutch cap and spermicidal cream, but these she will not use and her husband considers his own methods of contraception good enough.

So far I feel that I have only scratched the surface of the problem, treating the various diseases of squalor as they appear. Probably the only measure which would alter the situation materially is to sterilise Mrs. Smith, to which I do not suppose either the Smiths or a gynæcologist would agree, and which I cannot persuade myself is really right ; it carries with it a great danger of encouraging promiscuity and breaking up the home.

I am anxious to take Mrs. S. into the local G.P. maternity home for her next confinement, her seventh. She has reached a dangerous degree of multiparity and I don't want to find myself dealing with a postpartum hæmorrhage or prolapsed arm in no. 13 Downtown. If the children can be looked after for a while I would like to keep her in hospital for a good rest, proper food, and a course of iron and vitamins, and have her teeth seen to. At the same time we can enlist the help of Mr. Smith to clean up the house. Would your department be able to help with the children ? A month's holiday at a children's home would do them the world of good.

But what can we do for the future ? I suppose we should be thinking about the schooling of Mrs. Smith's daughters. They are no brighter than she is, and are not likely to derive any greater benefit from a formal State education. What they need is a simple training in the elements of house-keeping and mothercraft in a special school for the handicapped, if they are not to follow in their mother's footsteps.

I look forward very much to discussing all these problems with you, for I badly need a conducted tour of the Welfare State, which is confusing to the untutored traveller.

Yours sincerely,

W. BREWER.

Public Health

Infantile Gastro-enteritis in Exeter

DURING the eight months from July, 1953, to February, 1954, there were 21 cases of gastro-enteritis in babies under 1 year who were being treated in, or had recently been discharged from, the Royal Devon and Exeter Hospital. 6 of the babies were in the maternity nursery, and the remaining 15 were patients in the children's ward ; but in only 4 of these 15 did the infection show itself in hospital. In the other 11, symptoms did not develop for periods ranging from a few hours to ten days after discharge ; 7 of the 11 fell ill within two days. It may be that a few of these cases were infected after discharge. There were 3 deaths in the hospital, and 2 more babies died in an isolation hospital. In every fatal case there was some other substantial contributory factor which aggravated the infection : thus, 2 of the babies were grossly premature (3 lb. 4 oz. or less at birth). *Escherichia coli* 0-55 was recovered from 8 cases, and no other pathogen was discovered. Gastro-enteritis was prevalent in the area during the period and *Esch. coli* 0-55 was isolated from some of these outside cases. During the same period, apart from 4 children readmitted because of gastro-enteritis occurring after discharge, 4 cases of gastro-enteritis were admitted to the hospital, 3 of them in December (12 of the infections in infants occurred during December and January). These admissions may have kept the infection "alive."

The whole outbreak is an example of a creeping epidemic with a number of apparently disconnected episodes and, therefore, not readily recognisable at the time. Crowding of the maternity ward and nursery has caused anxiety for some time, and, on the advice of the pædiatrician and the hospital's standing committee on cross-infection, a small isolation unit for children and a small premature-baby unit are being provided by the conversion of certain rooms. The committee is also reviewing the whole outbreak, and a report is being prepared for the regional hospital board and the Ministry of Health.

In England Now

A Running Commentary by Peripatetic Correspondents

As a passive amateur of the arts I always envy the active amateurs who open the piano, ring up the curtain, or seize the paintbrush with their own hands. To this courageous body belong, of course, the members of the Medical Art Society, and judging by their exhibition (at Walker's Galleries, 118, New Bond Street, London, W.1, till May 8) they have all had an enjoyable year, with a good deal more to show for it than I have.

To begin at the beginning, Sir Philip Manson-Bahr, appropriately maintaining the equine tradition of another president, contributes a study of his black hunter *Merrymack*; and I also liked the feathered flurry of his *Ducks and Drakes*. The landscapes were varied and accomplished. I recall with pleasure Sir Harold Gillies's brown and white study of *Beech Trees in Snow*; the rust and grey roofs on T. M. Ling's *Beddingwood Farm, Sussex*; the flat placid pattern of church and water in R. Ogier Ward's *Friston Church*; the space and the snow of A. M. Rackow's *Cumbrian Farm*; the purple shadows of E. M. Whetnall's *Santa Barbara Mission*; the inviting turn of the street in Henry Wilson's *Standon Village*; the black figures of three Negroes walking down a near-black road in M. G. Corco's *Near Oji River*; the effectively scrawled red-ink roofs and roads of Isabel Wilson's wide countryside in *Flight over Europe*; and the path through a dark wood in Ian Robin's *The Glen*. Clearly there are some seafaring folk among the society; A. S. Till saw *The Blackwater at Malden* as a pleasing study in blues and yellow, and T. Holmes Sellors shows us furled rust sails at *Ipswich Docks*.

Among the portraits W. Hartston's studies of Africans stand out, especially the profile *Ahmed*. In Lady Whitby's *Freda* the red, white, and green of the figure is supported by a background of dull blue and pink. Denis Cronin has contributed several small sensitive bronze heads.

The still lifes ranged from N. Newman's pleasing but restrained vegetarian arrangement of two spring onions, two Spanish onions, two carrots, and three pea-pods, to the eerie assortment of fungi in J. F. Stokes's *Conference*. Norman Ashton suggests a satisfactory *Design for Living*: his simple bread and cheese and boiled egg stand beside a brilliant microscope, graceful glass flasks, and the ophthalmologist's bottle of atropine, and behind it all a beautiful decorated plate. Lady Whitby's bottle, mug, red book, and knitting-needles backed by grey rugs suggests a simpler but also attractive way of life.

The implicit social criticisms of these pictures is explicit in B. N. Brooke's *The Choice* (a woman faced with three hellish hats); and in M. Partridge's *Evening—North London* which shows Mrs. Battle of Golders Green at the bridge table. Nor has the new wirework trend been neglected, and in the *Unknown Political Stunt* S. Hales offers his views on the National Health Service. Cecil Ruben's *Bar at the B.M.A.* looks inviting, but I think the one at the Folies Bergère still has it.

My 2³/₄-year-old was drawing long lines all down her page. "This is a Zebwa Cwossing . . . but all the other animals can use it too."

I am still vaguely worried about Easter Monday. It was a beautiful sunny day and we all went to Plumpton Races. We got a good place for the car on the hill, just in time to watch the first race. Then I explained the horrors of betting to the boys, but said it was all right to put a small amount on a horse, if you could afford to lose that much, to give you an interest in the race. I had never backed a winner, I did not know the name of a single horse there, but I was going to put something on one for the second race, to have a horse to watch.

I had a newspaper which recommended Rowley Boy. Waiting my turn at the tote, I saw that one of the other horses was The Editor, and being an editor (of a small specialist journal) I put my money on him, and a very nice race he ran, winning the two-mile steeplechase by two lengths. After

collecting 17s. 10d. I explained to the children that if one betted, which of course one shouldn't really, and was lucky enough to win, one must not let it go to one's head, and double up. I then departed to place a small-amount-that-I could-afford on Glim and Dim, the paper's selection for the next race. With ten seconds to spare I discovered the horse was not running, and glancing like lightning down the card, I saw that Athelney, very near my mother's old home in Somerset, had that lucky number 13. This fortunate coincidence brought me 16s. 2d., although I had been watching the wrong horse as Athelney's jockey's colours looked sea-green instead of turquoise. I explained to the children that it was wrong to be carried away by betting, that two was a coincidence, but it took three to make a syndrome, which I hoped they would think was a particularly wicked sort of sin.

I had to leave rather hurriedly to place my bet on the next race, the Abergavenny Challenge Cup, but I saw that there were only six runners and reasoned that each of them had a chance of a place. I selected Nome, as for years I wanted to go to Alaska. He turned out to be a lovely dark slim creature, frisky and heartening. He had the inside place, got the lead, and kept it. The favourite challenged him in the last half-mile but fell. Refreshed by this little coup (£2 0s. 8d.), I determined to lose next time by backing the outsider, Distani, but found my wife had the same idea and so gave the newspaper expert another chance—Diego Rubio was his choice. Distani, a little horse, led to start with, but of course Diego Rubio won.

I started to tell the children about betting, &c., but caught a cynical look in the eye of the eldest, and shut up. He said that he was going to bet this time, on Never Again (by Boozer's Gloom out of Officers' Mess). I declared for either Western Slipper or Windsor Light, but as I approached the tote window I thought everyone who wasn't on either of them was on Le Serpent, so I simply backed the favourite, Retlaw, and went to watch the race. The issue was at no time in doubt. Never Again was second.

The real tragedy is that I didn't double up, but what worries me is that although I don't know enough to work out whether picking five winners in a row is statistically significant, it looks it. And if it is, there is something queer about statistics, considering my methods of choosing winners. Perhaps the real solution is that there is something queer about racing. The only conclusion I can draw is that if you follow your nose you and your family may have a day at the races for nothing. Of course you must have the right nose, like those chaps with clinical intuition.

* * *

Whether Her Majesty's Government would consider helpful advice from the U.S.A. to convert the alleged loss of the second battle of Trafalgar¹ into a victory, or at least a stalemate, I don't know. But I venture to draw their attention to a recent communication on the Use of a Specific Sound to Repel Starlings (*Sturnus vulgaris*) from Objectionable Roosts.²

The authors found that when starlings were held by the legs or wings, they emitted a piercing shriek. This distress call caused other starlings to leave their roosts and not return even after some months. This suggested that a recorded distress call might be used as a repellent. Accordingly, wild starlings were induced to give distress calls by holding their legs and shaking them roughly. The calls were recorded with a tape recorder. When the distress call was broadcast a heavily infested roosting area was cleared in 4 nights.

But I'm not clear whether that segment of Her Majesty's Government that has to maintain the traditions of Trafalgar, Nelson, et al. would consider a victorious end worth the employment of such one-sided means as holding the starlings' legs and shaking them roughly; or would agree with my implied classification of Trafalgar Square and appurtenances as "objectionable roosts."

Diagnosis in the Bus Queue

1ST LADY: "Have you been to the doctor's yet?"

2ND LADY: "No, not exactly. You see, I'm goin' an' I'm not goin'—that's how I am."

Letters to the Editor

THE BOMBS

SIR,—Many of your readers had been eager to hear your comments on the situation revealed by the recent "successful" experiments with hydrogen bombs; but some of us were conscious of an element of disappointment in our reactions on first reading your leading article of April 17. You did not try to present us with an analysis to which we could expect a large majority of our profession to agree. You did not put before those who crave decision and action a clear-cut choice between a heroic disarmament and an all-out support of the American policy of "negotiation from strength." You did not even encourage us to believe that members of our profession have as such no special duty in this matter.

But you did remind us that doctors are accustomed, more than most people, to face the facts of a dangerous situation realistically, and to do their best for everyone involved in the danger; and that a realist need not be a cynic. Realists who point out that war, having lost its survival value, is unlikely itself long to survive, seem to be on unassailable ground; the trouble is that it may nevertheless survive long enough to destroy all that we value in our world, and perhaps life itself.

Dr. Duncan Leys and Dr. Alex Comfort, in their letters last week, express grave doubts about the emotional balance of those in control of thermonuclear research in America. Dr. Leys thinks that "neither fear of retaliation nor any moral considerations will restrain the desperate"; he implies that those in effective control of thermonuclear weapons in the U.S.A. are, or may become, so desperate with guilt-ridden fear as to be inaccessible to any rational restraint; and there is evidence to support such a view. At least there can be little doubt that ever since the comparatively harmless pioneer atomic bombs were dropped on Japan there have been evidences of abnormal guilt-reaction in America. The danger of the devastation of Britain by hydrogen bombs or other thermonuclear weapons is vastly greater than the corresponding danger in America, while the fear-reaction is greater in America.

Dr. Comfort uses the ugly word "paranoia" in referring to the mentality of those who inspire and direct these activities; similarity between the emergent action and that recognised in individuals as paranoid is certainly striking. There is the same persisting terror of persecutory aggression, the same unrestrained violence of defensive response to it, the same effective planning in complete secrecy. It will be said that the paranoid protects himself against non-existent dangers, while the enmity directed against the U.S.A. is real; and there is evidence of emotional imbalance in Russia too. However true this may be, it emphasises beyond everything else the need for the sane and benevolent forces in the world to assert themselves.

It is common knowledge that when all are afraid, as before the outbreak of a panic, those who are most afraid take the lead. I have become accustomed to think of fear and flight as the least worthy emotional reaction to danger, with escape to anger and counter-aggression as a more admirable, as well as a more comfortable, alternative. It is perhaps unreasonable to expect a group which has risen from fear to successful aggression voluntarily to abandon a security based upon fighting strength in favour of a greater security which may have the appearance of weakness. But the urge to survival, applied through the less frightened and more rational members of the community, may supply the necessary compulsion; and there is for the individual, and no doubt for a nation, a stronger defence than counter-aggression. If he can find courage enough to study, without preconceived fear and enmity, the motivation of his enemy, he can usually—not always—

find so much in common with his own that the mutual enmity is mutually disarmed, to the benefit of everyone concerned.

Those who have never used this method cannot be expected to value it, but they might nevertheless be ready to see that pride in fighting-strength may not be the final consideration in human values. It seems that the time has come to revise that valuation, in the interests of our friends and of our enemies as well as in our own. Personal pride, classified by Aristotle as a virtue, is a vice by Christian standards; national pride may be due for a similar revaluation. I like to feel still at liberty to be proud of our national achievements, and I would certainly find conquest from abroad more offensive if the occupying troops were non-English-speaking; but I should like to place it on record that if given the choice between this and victory over the foreigner by the snuffing out of his civilian population I should hope and expect myself to choose the former.

London, W.1.

J. NORMAN GLAISTER.

SIR,—Dr. Comfort's letter based its main argument, however sincerely, upon a major misconception. No matter how much one may detest war and desire reconciliation between nations, it is sheer speciousness to infer that for Britain there is less menace from Russia than from the United States. The North Atlantic Treaty Organisation is probably the only thing that has stood between Russia and the subjugation of Western Europe, and to attempt to confuse this particular issue is to play into the hands of Communist propaganda. Quite apart from this, it is a matter of historical fact that it was the United States who proposed, and still propose, international control of the production and development of atomic weapons, while the Soviet Union have consistently refused to accept such control.

For Britain now publicly to dissociate herself from her greatest ally—for that is what Dr. Comfort's proposition would in fact amount to—would be to present the world as a free gift to tyranny. *Of course* we must continue to press for international control and inspection of all atomic weapons, with a view to their ultimate abolition—and we should be well advised to extend this to submarines and rockets, both of which are the subject of intensive Soviet research and would be obvious weapons to deploy against our island. More important still, we must do all we can to achieve a permanent reconciliation between nations. But to suggest in this context that we have no more reason to trust the United States than the Soviet Union is precisely the kind of misguided propaganda which Dr. Comfort so rightly deplures.

Guy's Hospital,
London, S.E.1.

DAVID STAFFORD-CLARK.

SIR,—I wonder how many people really believe that the hydrogen bomb is a blessing in disguise, that it presents a compelling safeguard beneath a horrible threat? Politicians in plenty are expressing this curious idea, and Professor Haddow's appeal to a more enlightened section of society is amply justified on this ground alone. The potential blessing of so uncontrollable a weapon will surely escape the comprehension of men and women who have been nurtured on Christian ethics and Greek culture. The humanitarian professions, then, are armoured against such dangerous heresies; it is mainly from them that any resistance to a universal moral landslide must derive.

There must be many within medicine and its outlands who, having long held that the desperate state of human affairs has sprung from a lack of religious faith (Christianity in particular), now see a second cause—mental aberration. Dr. Comfort is one of a great company who hold this a very serious development. The priest and the psychiatrist must now work hand in hand for the healing of the nations. All who face the ideal of physical, mental, and spiritual health must find a new poignancy

in the situation, for today the power of a psychopath in a high place is such that he need ask no man's leave before he precipitates horrors.

There are millions of sane and charitable human beings whose endurance must outlast that of Damocles. Most of them are lonely and inarticulate; they derive new hope and vigour from any who will stand up and voice their fears for them, and convince them that their thoughts are in fact being broadcast and therefore not hopelessly drowned in the shouts of maniacs. There is some sort of moral obligation upon those professional men and women who believe that mankind must settle its disputes peacefully to express the goodwill and the moral scruples of the inarticulate, for theirs is the authority and the ability, by reason of the service they render to society. Only if such men and women accept this responsibility and act upon it, will there be mobilised a force capable of outlawing war itself and seizing, at this eleventh hour, our one chance of civilised survival.

Southmead Hospital,
Bristol.

PETER COOPER.

TUBERCULOSIS YARDSTICKS

SIR,—Dr. Stewart and Dr. van Zwaenenberg, in their letter of April 17, have drawn attention to a difficult and topical problem—namely, the criteria which should now be adopted in assessing the “activity” of a case of pulmonary tuberculosis. They suggest that assessment must depend largely on the results of bacteriological examination, but they then proceed to produce some evidence which implies that bacteriology is no longer wholly reliable. We are certainly becoming increasingly familiar with the patient who presents the X-ray appearance of cavitation coupled with an impressive series of negative sputa, and as a result the *cachet* formerly conferred by the production of a negative culture or animal inoculation test has lost a little of its lustre. It is perhaps going too far to say that such desirable bacteriological findings can be produced at will by juggling about with the chemotherapy; but they can be influenced very appreciably, and consequently negative bacteriological findings should now be accepted with great reserve, unless the clinical and radiological evidence is completely in keeping.

In the official definition of quiescence pride of place is given to improvement in the patient's general condition, to the absence of toxæmia, and to negative sputum examinations, while the evidence provided by other clinical examinations and by serial radiographs brings up the rear. A readjustment of these criteria is overdue; and, while all the factors mentioned should continue to be given adequate consideration, increasing emphasis might with advantage be placed upon the radiological findings, including tomography, which at present appear to be the most reliable index of potential infectivity which we possess.

If the number of patients admitted to hospital for the treatment of pulmonary tuberculosis, who have received chemotherapy before any attempt has been made to confirm the diagnosis by sputum examination, can be accepted as a guide, then the popularity of bacteriological investigation has declined even further than many of us would have supposed.

Red Cross Sanatoria of Scotland,
Tor-na-Dee, Milltimber, Aberdeenshire.

R. Y. KEERS.

TUBERCULOSIS IN ADOLESCENCE

SIR,—Most of the measures Dr. Bentley suggests in his letter last week are, of course, long overdue, largely because the dangers of an unrecognised primary infection during puberty are not always appreciated, because the value of B.C.G. in preventing adolescent phthisis^{1 2} is

1. Hyge, T. V. *Acta tuberc. scand.* 1949, 23, 153.
2. Wallgren, A. Tuberculosis and other Problems of Pediatrics. Baltimore. 1950.

underrated, and because the relative rarity of the disease is allowed to conceal its importance. (In England and Wales 3–9% of children dying between the ages of 10 and 14 years do so as the result of respiratory tuberculosis.) Incidentally, the “inevitable deterioration” mentioned by Dr. Bentley is distressingly obvious in recorded experience of the disease: half the patients used to die within 2 years, and three-quarters within 5 years, of diagnosis.

The use of tuberculin testing before mass radiography is obviously rational, and probably economical. It should prevent the false sense of security sometimes engendered by a report that the chest radiograph is normal in a tuberculin-negative adolescent. The measures suggested (tuberculin testing, radiography, and vaccination) may be criticised as impracticable, uneconomical, and unnecessary. But they would certainly be more rewarding than, for example, the prolonged surveillance of healthy tuberculin-positive children between the ages of 5 and 10 years, still practised in many centres. Moreover, disease discovered at the asymptomatic stage is likely to be amenable to treatment within a reasonably short time, thus avoiding the expense of a long stay in hospital (providing too sanguine a view is not taken of minimal lesions³). Furthermore, the final years of school life are the last occasions when all the youth of the country is readily available for epidemiological study and the practice of preventive medicine on a large scale.

Dr. Bentley's suggestions should be implemented first in girls' schools, for phthisis is 3 times more common in girls than in boys between the ages of 13 and 15 years.⁴

In North-eastern England most children who develop this adult type of pulmonary tuberculosis are treated at one centre (Poole Hospital, near Middlesbrough). Here, as recommended by the National Association for the Prevention of Tuberculosis,⁵ the children's hospital is not isolated, but is an annexe of the main establishment, which is fully equipped for thoracic surgery. A recent survey⁶ of cases seen at this centre showed that early diagnosis and chemotherapy, combined with rational collapse and surgical procedures, have more than trebled the immediate expectation of life in childhood phthisis. But prevention is still far better than cure.

Bishop Auckland.

J. P. ANDERSON.

CANADIAN APPOINTMENTS

SIR,—Your issue of March 27 contains an advertisement for a consultant post in Canada at a salary of \$10,000 per annum. The notice indicates that this is approximately equivalent to £3700 sterling.

I feel strongly that prospective candidates for the post should be made aware that in terms of living standards \$10,000 is equivalent to nothing like that sum. The present rate of exchange (\$2.80 to the pound) is unrealistic; to provide a closer approximation to reality a figure in the region of \$5.00 should be cited. This post, which appears to be far more highly remunerated than one of equal status in England, is thus very much on the same level. \$10,000 will provide a reasonable standard of living, but it is far from wealth: radiologists in private practice in this country can make two to three times that figure and commonly do so.

This is not the first advertisement in *The Lancet* to mislead British doctors with ambitions to emigrate by proffering apparently generous salaries in terms of dollars; but I believe it is the first to translate dollars into pounds in this way.

3. Anderson, J. P. *Lancet*, 1952, ii, 490.

4. Anderson, J. P. *Ibid.*, 1952, i, 876.

5. National Association for the Prevention of Tuberculosis. Design for Sanatoria. London, 1951.

6. Anderson, J. P. Phthisis in Childhood. M.D. thesis, University of Durham, 1953.

I would therefore urge, Sir, that some editing of Canadian advertisements be made, or that the large difference in the cost of living be drawn to the attention of applicants.

M.D.

Canada.

** A similar letter of warning about the cost of living in Canada appeared in our issue of Sept. 27, 1952 (p. 640).—Ed. L.

RHEUMATOID ARTHRITIS AND ALLERGY

SIR,—The inter-relationship of rheumatoid arthritis and various allergies has often been discussed, and any such claims have usually been rejected, as was the case of the statistical investigation by the Empire Rheumatism Council in 1950. The alternation, however, of various allergies, the duodenal syndrome, and psychoneurotic states is, I believe, not uncommon.

In an examination of the case-histories of 1000 rheumatoid arthritics, 6 were found in whom the arthritis began at exactly the time that an asthmatic state disappeared. Unfortunately, not every patient was specifically questioned about the presence or absence of any asthmatic tendency, and therefore no data are available about the incidence of asthma in this series. The occurrence of 6 cases in which rheumatoid arthritis appeared to replace the asthmatic state is of interest and seems to merit further investigation by others when analysing future series of cases. We would be very grateful to hear from anyone interested in either the rheumatic diseases or psychosomatic and allergic conditions, whether their experience confirms or refutes this finding.

G. D. KERSLEY.

AVERTING POLIOMYELITIS

SIR,—Now that the threat of poliomyelitis is again upon us, may I, like Cromwell, beseech you, in the bowels of compassion, to think it possible that it may be averted?

These facts are authoritatively stated:

- (1) "Poliomyelitis is an infection of the lining of the bowel, prone to pass more deeply into the body."¹
- (2) "Infection is only occasionally manifested by nervous illness."²
- (3) "There is now agreement that poliomyelitis is essentially spread by human contact and that stools form the main source of the virus."²
- (4) "Human faeces are the most significant source of the virus; the period of communicability may extend for longer than a few days after onset; the mouth is the usual portal of entry."²

The secret of the control of poliomyelitis is to make sure that all who are at risk from contact with a known case, direct or remote, shall have clean fingers after emptying their bowels. Anyone with a lump of wet mud and a piece of toilet paper can demonstrate how toilet paper is permeable to moist faeces and must allow the fingers to be contaminated at defaecation. One way to keep the fingers clean is to substitute cotton-wool for toilet paper or to use toilet paper in three thicknesses. Another is to use an effective antiseptic. The virus of poliomyelitis "is readily destroyed by oxidising agents such as hydrogen peroxide and potassium permanganate,"³ and an ounce of permanganate crystals, costing 5d. will make fifty gallons of potent solution. I suggest that by the side of every school and public lavatory in a threatened area we should place permanganate solution in 3-lb. jam-jars. On the toilet paper should be printed some simple words such as these:

This district is threatened with the disease called poliomyelitis. The germ that causes this illness lives in the bowels

1. Burnet, F. M. *Brit. med. Bull.*, 1953, 9, no. 3.
2. Rhodes, A. J. *Ibid.*
3. MacCallum, F. O. *In Viruses and Rickettsial Diseases.* London, 1950.

of ordinary men, women, and children, but only a few of them become ill. These germs are so small that they can easily get through a piece of toilet paper, so use it in three thicknesses. Then dip your hands in the jar of red water by the lavatory seat for a few moments. Then with wet hands pull the chain and open the door, and go and wash them thoroughly.

The matter could be made an interesting subject for science lectures in schools. Science masters and mistresses and their pupils should undertake the meticulous management of school lavatories; there is nothing degrading in fighting the causes of death and crippledom, and there need be as little sentiment on this subject as there is on any other part of the sewage system. Above all there should be the enthusiasm of a campaign—a campaign for a season, against a known enemy and with clearly defined methods of confining it.

In the broad stream of infection by poliomyelitis few are stricken: if we narrow the stream, fewer will be stricken; in the presence of a virulent strain this narrowing is a matter of grave urgency.

Beckley, Rye.

C. G. LEAROYD.

TREATMENT OF VARICOSE ULCERS

SIR,—I agree with Dr. Rivlin (April 17) that the key to success in healing gravitational ulcers is adequate elastic support, but the elastic support need not be maintained by an adhesive bandage. Over ten years ago, woven elastic web bandages were introduced in our department by my colleague, Dr. H. R. Vickers, and we have found that they have all the advantages of an elastic adhesive bandage with none of the disadvantages of skin sensitisation or the sweat-retention syndrome.

The bandages are put on like a puttee from toes to calf; they have the advantage over elastic stockings that at the part where most support is needed, around the malleoli, extra turns of bandage can be applied if necessary, and any form of dressing can be used on the ulcer area.

One important feature is that most patients will continue to wear the bandages after the ulcer has healed. They come to look on them as a talisman which keeps the ulcers away, and the relapse-rate is considerably out down.

I have never been able to discover why these bandages have not been used more generally in this country.

Rupert Hallam Department of
Dermatology, Sheffield.

I. B. SNEDDON.

SIR,—May I reply to the letter from Mr. Murley (April 10)? In doing so, I shall be replying too to Mr. Roland Jones and Dr. Rivlin (April 17) and Mr. Rowden Foote (April 24).

Firstly, there is the question of arterial spasm accompanying a deep thrombosis. I believe that arterial spasm does occur in deep thrombosis, and my belief is based on clinical observation.

I have observed that, in many patients giving a history of deep thrombosis from whatever cause, the toes are often cold and blue, indicating diminished blood-flow to the periphery. I have also found that there is very often a poor femoral pulse, and in some cases no pulse at all. Furthermore, I have sometimes been unable to introduce a fine needle into the artery, when attempting to inject tolazoline ('Priscol'), because the vessel was too small. Again, to prove that arterial spasm does exist, I have performed a clinical test in many cases. A skin thermometer is applied to the thigh and another to the dorsum of the foot; and the intra-arterial injection of tolazoline is then given. In nearly all cases the thermometer on the thigh shows a rise in temperature, and a great many show a rise in temperature in the foot as well.

The second point Mr. Murley raises is the question of lumbar sympathectomy for varicose ulcers. I myself have never done this operation for varicose ulcers, and in my letter of April 3 I do mention that, in the often

fat and flabby patient who has a varicose ulcer, a lumbar sympathectomy would not be without its risk. But lumbar sympathectomy does (and Mr. Murley will, I am sure, agree with me) raise the temperature of the limb. The first answer I get from a patient who has had a successful lumbar sympathectomy always confirms that the limb feels warmer. It is also taught that sympathectomy has its maximum effect in dilating the skin vessels as opposed to the vessels of the muscles and other deeper structures. Surely an increase of skin blood-flow will promote healing of skin ulcers? Tolazoline will temporarily have the same effect as a lumbar sympathectomy.

Mr. Murley's third point is the question of pain in leg ulcers. I have observed that in many women the pain is worse before ulceration has occurred. The pre-ulcerated leg feels hard and brawny in its lower third, and sometimes the pain is so severe that the patient is reluctant to let anyone touch the leg. In contrast to these painful brawny legs ("inverted Guinness-bottle legs") there are those with considerable ulceration where pain is slight or even absent. Surely it is the strangulation of the leg inside the resistant skin which is giving rise to this dreadful pain.

Finally, I would like to say something about skin-grafting of ulcers. One has to be guarded in saying how long a graft will last, for many do break down sooner or later. The darn graft which I have mentioned elsewhere, and which I believe originates from an idea of Mr. Dickson Wright, has a place in the treatment of varicose ulcers. Its main use is in those ulcers which are wide in area and which are not punched out. The punched-out ulcer, on the other hand, is more difficult to heal, and should respond better to hyaluronidase plus injections into the femoral artery. I must make it clear that I advocate this treatment only when compression bandaging is not having the desired effect. As I said in my letter, firm bandaging still remains the basis of all treatments, and it is when healing is slow or non-existent that I advocate these extra measures.

London, W.1.

MAURICE LEE.

SPONDYLOSIS

SIR,—In his Heberden oration, published in your issue of April 3, Sir Russell Brain has given a brilliant exposition of disc lesions at the different spinal levels. He draws particular attention to the dural root-pouch—an important structure in explaining symptoms. Clinical grounds had enabled the presence of this pouch to be inferred¹ and the deduction drawn² that at lower lumbar levels the investment is not less than an inch long.

Sir Russell points out that disc lesions give rise to pain that appears to follow the myotome rather than the dermatome, but this is not the full explanation. Dural reference is often entirely extrasegmental and, when pressure is exerted on the dura mater, the symptoms often spread far beyond any relevant myotome. Thus, an early cervical disc lesion at any level may give rise to pain spreading to the head (C1-2 dermatomes) no less than to the scapular area (T3-6 dermatomes). Similarly, the pain arising from the dura mater³ in lumbago caused by, say, a 5th lumbar disc lesion, often reaches to the mid-thorax posteriorly, or to the abdomen, or to the groins, or to the coccyx, or to any aspect of the lower limbs. This represents reference far beyond both dermatome and myotome.

When the protrusion moves a little to one side, the dural investment of the nerve-root comes to be compressed. Now segmental reference appears, occupying

the myotome proximally and the dermatome distally. By contrast, impingement on a nerve-trunk seldom gives rise to any local symptoms at all. Constant pressure leads to a painless paresis; intermittent pressure to distal paræsthesiæ (most severe during a period of recovery), in due course followed sometimes by vague aching in the affected limb.

This difference in the order in which symptoms appear provides a useful pointer in diagnosis; for pressure on dura mater and then nerve-root leads to pain in the trunk (though often in the "wrong" place), later spreading to the limb, whereas local discomfort is absent when a nerve-trunk is compressed.

The practical lesson to be drawn from Sir Russell's research on cervical myelopathy is that cervical and thoracic disc lesions are potentially dangerous. Hitherto it has been the practice to leave early protrusions to themselves, to get larger or smaller as fortune dictates. If, however (as has been the practice at St. Thomas's Hospital in our department for the last ten years), all cervical and thoracic disc lesions are reduced early on—when reduction is easy—the posterior longitudinal ligament escapes prolonged stretching and the likelihood of eventual myelopathy will clearly be diminished. Careful manipulation without anaesthesia during traction scarcely ever fails when the protrusion is small and recent, and it now appears to be not merely the useful pain-relieving measure I have so far regarded it as, but of far greater importance in the prophylaxis of eventual crippledom. Happily, therefore, Sir Russell's research points to an immediate therapeutic application.

London, W.1.

JAMES CYRIAX.

CLINICAL TESTS FOR KETONURIA

SIR,—The article by Dr. Nash and his colleagues in your issue of April 17 cannot be allowed to pass without comment. They describe the advantages of a tablet test for ketone bodies in the urine, and this is a praiseworthy contribution to chemical pathology. But they think it necessary to introduce a contrast by decrying the ways of discovering ketonuria used hitherto.

They state that there is uncertainty as to whether the colour given by the nitroprusside reaction is due to acetone or due to aceto-acetic acid. It has, in fact, been known for many years that the colour in the test is given by both compounds, but that the sensitivity of the test was such that it gave stronger reactions with aceto-acetic acid. Hurlley gave an elaborate account of the tests for acetone and aceto-acetic acid in *The Lancet* in 1913.¹ He pointed out that the Rothera test was about 20 times more delicate for aceto-acetic acid than acetone. Cole,² in the 5th edition of his book on *Practical Physiological Chemistry*, states that acetone can be detected at 1:20,000 and aceto-acetic acid at 1:400,000.

The authors find that the Rothera test is too sensitive. Kennaway showed in 1913³ that the speed of colour development depended on the aceto-acetic acid concentration. If this was 1 part in 200,000, the pink colour did not appear for some minutes. Ever since, it has been accepted that what Kennaway called the "slow-weak" reaction (i.e., when the colour does not appear for some minutes) was of no clinical importance.

The statement that Harrison⁴ does not "indicate that the urine must be saturated with ammonium sulphate to give the maximal sensitivity" is incorrect. He explicitly writes: "Saturation with ammonium sulphate removes interfering substances making the test more delicate."

Dr. Nash and his colleagues say that few textbooks adequately describe the details of Gerhard's test: in fact, Harrison's textbook,⁴ which is only one among many, states the exact strength of ferric chloride to be added in the test—namely, 10%—and the quantity is described as "sufficient

1. Hurlley, W. H. *Lancet*, 1913, 1, 1160.

2. Cole, S. W. *Practical Physiological Chemistry*. Cambridge, 1919.

3. Kennaway, E. L. *Guy's Hosp. Rep.* 1913, 67, 161.

4. Harrison, G. A. *Chemical Methods in Clinical Medicine*, London, 1947.

1. Cyriax, J. *St. Thom. Hosp. Rep.* 1949, 5, 68.

2. Cyriax, J. *Orthop. Med.* 1954, 1, 382.

3. Cyriax, J. *Lancet*, 1945, 11, 426.

drops to be added to completely precipitate the phosphates." It is well known that any excess of ferric chloride is liable to render the test insensitive. In the same textbook it is said that boiling is to be *thorough* (italics by Harrison), and it is specifically stated that it should be done in a boiling-tube or open vessel. If the writers are correct (and we are prepared to doubt this) that the boiling is usually done only momentarily in a narrow test-tube, this would be quite contrary to the established descriptions of the technique. A recent article⁵ goes as far as emphasising the need for prolonged boiling by prescribing a 50% evaporation.

We are looking forward with interest to the advantages of the tablets described, but we maintain that the present tests for ketonuria are effective, and also that, as far as we know, they are adequately performed throughout the country. The tablet test appears to be in fact a "dehydrated," slightly less sensitive Rothera test. If this was so, it would have no advantages in the laboratory but might be found to be convenient in the consulting-room.

Department of Pathology,
St. Bartholomew's Hospital,
London, E.C.1.

H. E. ARCHER
H. LEHMANN.

SIR,—In an otherwise excellent and informative article Dr. Nash and his colleagues seem to have overlooked a simple expedient for reducing the sensitivity of Rothera's test—namely, dilution. A 1 in 5 dilution of urine brings the test into the desired range of sensitivity and, for students, perhaps this is a useful manoeuvre. In practice, however, the rate of colour development is a sufficiently reliable index for the experienced.

Secondly, no mention is made of the use of a crystal of sodium nitroprusside, which, as far as I know, is reliable, is certainly simpler, and probably saves several seconds.

Department of Clinical Pathology,

PRESCRIBING AUREOMYCIN

SIR,—I wonder how many of your readers in hospital practice know that aureomycin cannot be prescribed by the general practitioner except by a very devious route—a restriction which applies neither to erythromycin nor to chloramphenicol. The effect can only be to further the use of an antibiotic known to be associated in some cases with the development of blood dyscrasias,⁶ where antibiotics carrying no such risk are equally effective. The continued existence of this regulation is a matter of grave concern.

Wallington, Surrey.

H. BARRIE.

NURSING BY THE MOTHER

SIR,—Dr. Lowenfeld, in her letter of April 10, urges the need for fresh and creative thinking on the treatment of sick children in hospital. The Nuffield Provincial Hospitals Trust shares this view and has, in fact, initiated a study on the care of children in hospital. This study will be made on behalf of the Trust by the Nuffield Foundation's Division for Architectural Studies, the establishment of which was announced in your issue of Feb. 6 (p. 319).

This study of the child in hospital will follow the lines established by the Trust's investigation into the functions and design of general hospitals. These were similar to those suggested by Dr. Lowenfeld—that is, preliminary research by a team of people with appropriate experience, followed by experimental building to test and demonstrate the conclusions. It is hoped that work on this project will begin in the autumn of the present year.

L. FARRER-BROWN
Director of the Nuffield Foundation.
London, N.W.1.

Obituary

WILLIAM HENRY SNYDER NICKERSON

V.C., C.B., C.M.G., M.B. Manc., D.P.H.

Major-General W. H. S. Nickerson, a former director of Army Medical Services in India and one of the distinguished band of medical holders of the Victoria Cross, died at his home at Kintyre, Argyllshire, on April 10.

He was born at New Brunswick, Canada, in 1875, the son of the Rev. D. Nickerson. He came to this country to go to school at Portsmouth Grammar School, and to study medicine at the Victoria University of Manchester, where he graduated M.B. in 1896. Two years later he joined the R.A.M.C., and he served in South Africa from 1899 to 1902. He was repeatedly brought to notice for good work done under fire in the battle of Stormberg and elsewhere, and in 1900 he was awarded the V.C. and promoted captain. The following citation describing the award appeared in the *London Gazette*:

"At Wakkerstrom on the evening of 20 April 1900 during the advance of the infantry to support the mounted troops, Lieut. Nickerson went in a most gallant manner, under a heavy shell and rifle fire, to attend a wounded man, dressed his wounds, and remained with him until he had him conveyed to a place of safety."

In 1909 he received his majority, and during the 1914-18 war he served at first in France, taking part in the retreat from Antwerp and in the battles of Ypres, Neuve Chapelle, and the Somme. In 1915 he was transferred to Salonika and later he served with the Egyptian Expeditionary Force as D.D.M.S. For his war services he was appointed C.M.G. in 1916, and C.B. in 1919. He also received the Greek Medal for Military Merit.

His promotion had been rapid, and he attained the rank of major-general in 1925 at so early an age that he was allowed to postpone his retirement for four years, during which he served as director of medical services in India. When he retired in 1933 he was made colonel commandant of the R.A.M.C., an office which he held till 1945. During the late war he was medical officer to an Atlantic convoy, to the Port of London Authority River Emergency Service, and with the Home Guard.

A colleague writes: "It was most fortunate that Nickerson was appointed director of medical services of the Army in India when he was, because it was largely due to his influence that exceptionally cordial relations were established between the civil and military medical services. But for this it would not have been possible to offer so effective a resistance to the attack made on both services by the retrenchment committee set up to cope with the severe financial crisis which occurred during these years. Insidious attempts were made to encourage and exploit conflicts of interests between the two medical administrations, both of which owe a great debt of gratitude to Nickerson for the part he played in their united defence of the policy of maintaining an adequate reserve of medical officers in India. Like the other medical friends of mine who have won the V.C., he was modest and unassuming, and utterly incapable of harbouring unworthy feelings of personal vanity. His selection on his retirement for the coveted distinction of colonel commandant of the R.A.M.C. reflected the affectionate esteem in which he was held by his fellow officers, and indeed by everyone who knew him well."

Major-General Nickerson married in 1919 Miss Nan Waller, who survives him with a son and daughter.

HAROLD PARNELL JAMESON

M.D., B.Sc. Birm., M.R.C.P.

Dr. H. P. Jameson, consulting physician in geriatrics to St. Albans City Hospital, died on March 31 at the age of 50.

In 1925 he graduated M.B. with first-class honours at Birmingham University, and after holding house-appointments at the General Hospital and Children's Hospital in Birmingham he moved to London, where he worked under Sir Robert Hutchison at the London Hospital and at Great Ormond Street. In 1928 he proceeded to the degree of M.D., choosing as the subject of his thesis the Remote Prognosis of Pneumonia in Childhood.

Diary of the Week

MAY 2 TO MAY 8

Monday, 3rd

- POSTGRADUATE MEDICAL SCHOOL OF LONDON, Ducane Road, W.12
4 P.M. Dr. Edwin Clarke: Cervical Spondylosis with Cord Compression.
- INSTITUTE OF CARDIOLOGY, National Heart Hospital, Westmoreland Street, W.1
9.30 A.M. Dr. K. W. Donald: Exercise in Heart-disease.
- INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5 P.M. Prof. G. Frontali (Rome): Proteins in Child Nutrition.
- INSTITUTE OF NEUROLOGY, The National Hospital, Queen Square, W.O.1
5 P.M. Prof. Klaus Conrad (Homburg-Saar): New Problems of Aphasia.

Tuesday, 4th

- ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
3.45 P.M. Prof. M. F. Lucas Keene: Development of the Pharynx. (Arnott demonstration.)
- INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. E. J. Moynahan: Urticaria.
- INSTITUTE OF NEUROLOGY
5 P.M. Dr. I. Wickbom (Sweden): Choice of Encephalography or Ventriculography for Examination of Intracranial Tumours.
- WRIGHT-FLEMING INSTITUTE OF MICROBIOLOGY, St. Mary's Hospital Medical School, W.2
5 P.M. Sir Wilfred Fish: Dental Research in the Inoculation Department.

Wednesday, 5th

- POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Dr. Martin Bodian: Hirschsprung's Disease and Chronic Constipation in Childhood.
- ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
3.15 P.M. Section of History of Medicine. Sir Charles Dodds, F.R.S.: Christopher Merritt (1614-1695), First Harveian Librarian. Mr. J. B. Oldham: Two Eighteenth-century Liverpool Surgeons—Park and Alanson.
- INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. Haber: Lichen Planus and Lichenoid Eruptions.
- MANCHESTER MEDICAL SOCIETY
4.15 P.M. (Medical School, University of Manchester.) Sir Heneage Ogilvie: Future of Surgery.
- UNIVERSITY OF EDINBURGH
5 P.M. (University New Buildings, Teviot Place.) Prof. Henry K. Beecher (Harvard): Resuscitation and other Early Care of the Severely Wounded Man. (Macarthur lecture.)
- MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. (18, Nicolson Street, Edinburgh.) Dr. A. G. Cruikshank Prescribing in General Practice.

Thursday, 6th

- ROYAL COLLEGE OF SURGEONS
3.45 P.M. Prof. G. W. Causey: Sterno-mastoid Muscle. (Arnott demonstration.)
- 5.30 P.M. Prof. G. A. G. Mitchell: Sympathetic Nervous System in Relation to Throat, Nose, and Ear.
- INSTITUTE OF CARDIOLOGY
9.30 A.M. Dr. Maurice Sokolow (California): Quinidine Therapy.
- UNIVERSITY OF EDINBURGH
5 P.M. Prof. Gerhard Domagk (Wuppertal-Elberfeld): Chemotherapy in Tuberculosis.

Friday, 7th

- POSTGRADUATE MEDICAL SCHOOL OF LONDON
2 P.M. Mr. E. T. C. Milligan: Surgery of Anal Canal and Fistula-in-ano.
- 4 P.M. Dr. Henry Miller: Allergic Disorders of Nervous System.
- ROYAL SOCIETY OF MEDICINE
10.30 A.M. Section of Otology. Dr. J. C. Seymour: Circulation of Cochlea. Wing-Commander P. F. King: Psychogenic Deafness.
- 2.30 P.M. Section of Laryngology. Mr. Dudley Ashcroft, Dr. A. L. Peeney: Management of Haemorrhage after Tonsillectomy.
- 5.30 P.M. Section of Anaesthetics. Dr. J. J. Bonica (Washington): Role of Anaesthetist in Management of Intractable Pain. Dr. E. H. Seward: Wasp Venoms and Anaesthesia.
- INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. M. S. Thomson: Lichen Planus.

Saturday, 8th

- SOUTH EAST METROPOLITAN REGIONAL TUBERCULOSIS SOCIETY
11 A.M. (Preston Hall, Maidstone, Kent.) Dr. A. Stoker (Illinois): Preferences in Surgery for Tuberculosis.
- MIDLAND TUBERCULOSIS SOCIETY
11 A.M. (Cheshire Joint Sanatorium, Loggerheads, Market Drayton, Salop.) (Joint meeting with North-Western Tuberculosis Society.) Dr. E. Snell, Dr. R. Walshaw, Dr. L. A. McDowell, Dr. George Luntz: What is the Place, if any, of Mass Radiography.
- 2.15 P.M. Dr. Clark Penman, Dr. T. W. Lloyd, Dr. G. S. Erwin, Dr. V. Cotton Cornwall: Analysis of Place of Artificial Pneumothorax in Treatment of Pulmonary Tuberculosis.

Births, Marriages, and Deaths

MARRIAGES

ZETLINE—ROBERTS.—On April 2, at the Paddington Registry Office, Dr. L. L. B. Zetline, of 16, Norfolk Place, Hyde Park, W.2, and Miss Jane Roberts, of 30A, Sussex Place, Hyde Park, W.2.

In 1929 he settled in practice at St. Albans with Dr. J. W. Hope Simpson, largely because of the opportunity for paediatric work offered by the children's beds at St. Albans City (then Osterhills) Hospital. He had full clinical charge of these beds for ten years, and the new children's block was built under his direction.

For many years he was medical officer to the Honourable Artillery Company, and a week before the outbreak of the 1939-45 war he was called up. He served in India, Teheran, and Ceylon. With the rank of lieutenant-colonel he was officer-in-charge of the medical divisions of Indian and British hospitals and consultant to a wide area.

After the war he returned to St. Albans, but shortly afterwards gave up his practice to take up his post as consultant in geriatrics at the St. Albans City and Hitchin Group of hospitals. He was a foundation member, and for the past year secretary, of the Medical Society for the Care of the Elderly.

An enthusiastic sportsman, Dr. Jameson was a keen and expert rider and he supported the Aldenham Harriers Hunt for over 20 years. He was medical officer to their point-to-point races, and to those of the Hertfordshire Hunt at Friar's Wash. Rock-climbing and mountaineering fascinated him, and only ten days before his death he had been rock-climbing in Wales with his eldest son. He was also a keen tennis player.

E. D. H. C. writes: "Jameson brought to his post as consultant physician in geriatrics at St. Albans and at Hitchin a definite and lively personality and outstanding organising ability. He had real sympathy for the needs of the sick, and I know that the general practitioners of the neighbourhood will feel the poorer for the loss of such a 'whole man' at such an early age."

In 1932 he married Joan Isabel Colthurst, who survives him with a daughter and two sons, the elder of whom is a medical student.

MATTHEW H. LOGG

M.D. Aberd.

Dr. M. H. Logg, senior physician and medical administrator of Grove Park Hospital, London, died on April 20 at the age of 56.

After graduating in 1921 at the university of his native city of Aberdeen, he became a house-physician at the Aberdeen Royal Infirmary, and in 1925 he proceeded to the degree of M.D. He came to London to specialise in tuberculosis work, and after holding a house-appointment at the Brompton Hospital he entered the service of the old Metropolitan Asylums Board at Colindale Hospital. In 1926 he was appointed to Grove Park.

His long tenure of office there was, in microcosm, the history of the tuberculosis service in London, to which he gave so much of his energies. He was particularly interested in the problem of pregnancy in the tuberculous patient. He contributed to many discussions on this topic, particularly at the British Tuberculosis Association, of which he was a founder-member; and he published a review of the subject in the *N.A.P.T. Bulletin* in 1946. His other writings included papers in our own columns on the use of para-aminosalicylic acid in pulmonary tuberculosis.

Dr. Logg leaves a widow.

Appointments

- BARRETT, AILEEN V., M.B., B.Sc. Glasg., D.OBST.: asst. M.O., area No. 4, Middlesex.
- FISHER, DOREEN M., M.B.: asst. county M.O. and school M.O., West Riding of Yorkshire (Batley and Heckmondwike).
- FITZPATRICK, R. H. P., M.R.C.S., D.A.: consultant anaesthetist, Sidcup and Swanley H.M.C. group.
- FLINT, F. J., M.A., D.M. Oxid, M.R.C.P.: consultant physician, Sheffield No. 1 H.M.C. group.
- FRY, E. N. S., M.B. Edin., D.A.: consultant anaesthetist, Tees-side H.M.C. group.
- HAGAN, J. G., M.B.N.U.I., D.P.H.: deputy M.O.H. and deputy principal school M.O., Northampton county borough.
- HICKEY, J. B., M.B.N.U.I.: registrar in ophthalmology, Norfolk and Norwich Hospital.
- JOHNSTON, N. G., M.B. St. And., D.A.: consultant anaesthetist, W. Durham H.M.C., Bishop Auckland General Hospital.
- KOTOWSKI, JAROSLAW, M.B. Polish School of Medicine, Edinburgh: senior casualty officer, Barry Accident Hospital.
- MACGILLIVRAY, R. C., M.B. Edin., F.R.F.P.S., D.P.M.: consultant psychiatrist, Little Plumstead Hospital.
- SANDFORD, F. M., M.R.C.S., D.A.: consultant anaesthetist, Dartford H.M.C. group.
- ZABORSKI, EDWARD, M.D. Warsaw: asst. orthopaedic surgeon, London Road Hospital, Boston.

Notes and News

EMPIRE RHEUMATISM COUNCIL

IN his report to the annual meeting of the Empire Rheumatism Council on April 28, Dr. W. S. C. Copeman, the chairman, paid tribute to the work of his predecessor, Lord Horder, who had held office since the inception of the Council in 1936. During the year a chair of rheumatology, the first of its kind in the Commonwealth, had been founded by the Council at Manchester University; and Dr. J. H. Kellgren had been appointed to this chair. In May, 1953, a medical deputation had been sent to the Minister of Health, in order to obtain a statement of future policy, and to secure Ministerial recognition of rheumatology as a speciality within general medicine.

Research activities continued to absorb the major part of the Council's slender financial resources. Work by Mr. A. A. Henly, F.R.D., at the Hospital of St. John and St. Elizabeth, London, suggested that in rheumatoid arthritis such changes in steroid metabolism as were found resulted from metabolic abnormalities associated with the disease process, and that primary adrenal dysfunction was not a causative factor in its development. Among other research projects one on the long-term treatment of rheumatoid arthritis, carried out by Dr. J. M. Tweed at the West London Hospital, was made possible by a Philip Gray fellowship founded by the Shell Petroleum Company. Two E.R.C. fellowships for specific researches had been awarded. One fellow, Dr. J. K. Norymberski, working at the chemical research laboratory of the Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases, had developed an analytical method for the simultaneous determination of formaldehydogenic and 17-ketogenic steroids, and a routine procedure for the estimation of the latter in urine.

The financial report reveals a total income in 1952-53 of £10,019 (exclusive of legacies), compared with £13,453 in the previous year. Medical expenditure was £8127, compared with £7220 in the previous year.

University of London

Dr. J. W. Landells, senior lecturer in pathology at London Hospital Medical College, has been appointed to the university readership in morbid anatomy at the college.

On March 24 the degree of M.D. was awarded to B. W. Lacey.

Ciba Foundation

Sir Macfarlane Burnet, F.R.S., director of the Walter and Eliza Hall Institute of Medical Research at Melbourne, will deliver a lecture at 5 P.M. on Tuesday, May 11, at 26, Portland Place, London, W.1, on the Problem of Virulence in Virus Disease.

Medical Women's Federation

The annual general meeting of this federation will be held on Thursday, May 6, at 8.15 P.M., at the Grand Hotel, Sheffield, when Dr. Annis Gillie will give a presidential address on Motive and Momentum.

Tribute to Dr. Thomas Anderson

A company of fifty attended a dinner held at Ruchill Fever Hospital, Glasgow, on April 20, to celebrate the 25th anniversary of the date when Dr. Thomas Anderson, now reader in infectious diseases in the university, joined the staff of Ruchill Sanatorium. Dr. James Lawson, medical superintendent of the hospital, presided. Prof. James Howie, proposing Dr. Anderson's health, remarked that his "powerful and successful resolve to upgrade the practice of infectious diseases was and is one of the real attractions of being a bacteriologist in the city of Glasgow." Professor Howie continued:

"Sometimes people say: 'Where are the great characters now?' The answer is that they have a different and a more difficult function to perform. Many of the great characters of the past were great dictators. Nowadays dictators are out of fashion. A great dictator in British medicine today would achieve only a great fall. Great achievement is harder today; it requires the patient man, the man who is able to sense the pace at which he can work the complex, still imperfect, still new, machinery of the health service. Our Dr. Anderson is one of these. His objectives are right, his ideals are high and unselfish, and he has a limitless capacity to hold on and to pull long and steadily in the right direction. Such qualities are less obvious and less spectacular than the fireworks of a great dictator. But the results may well prove to be equally valuable and perhaps of longer duration."

Gifts were presented to Dr. Anderson and to Mrs. Anderson, whose health was proposed by Dr. Peter McKenzie.

Royal College of Obstetricians and Gynaecologists

At a recent examination for the diploma in obstetrics the following were successful:

Pauline A. Adams, D. A. Aiken, D. J. M. Allan, N. J. W. Allan, G. A. Ames, W. M. Anderson, Liselotte Asch, Swayamprabha Bajpal, G. S. Banwell, D. W. Barnes, Rosalind A. Barnes, Margaret N. Barr, Mary M. Baxter, Jean M. Beccroft, Elspeth V. Beveridge, J. C. H. Bird, W. P. Black, A. S. Blake, Richard Blight, M. L. Bloom, F. P. Brown, J. W. Browning, Hilda M. Brunt, Marjory M. Buchanan, A. M. Burnford, Nancy I. Cardno, Kim Choy Chong, Marjorie Coates, Arnold Cohen, T. I. Cope, C. E. Cosgrove, Mary G. Coyle, Audrey N. Crocker, Kusum Amerchand Dalal, Charles Dansie, Alan Davies, Jean M. Davies, J. I. W. Davies, Joan V. Davis, G. B. Davison, V. E. Dean, J. Y. N. Devine, J. J. Devine, R. D. P. Druiitt, Bernard Dudley, Donnell Duffin, John Dunlop, C. P. E. Elliott-Binns, J. J. Enright, D. L. Evans, Mary E. L. Evans, Jeannette G. Eveson, M. A. Fenton, Isabella C. Ferguson, Jack Fine, Alison M. Fleming, Margaret B. Fox, Mary U. Franklen-Evans, J. A. Girling, Ivan Goldman, J. H. Goode, P. M. Goodrich, P. D. Grant, Elizabeth D. Grassie, Hilary A. Hagan, Elizabeth M. Haines, C. J. J. Herlihy, K. M. Hewitt, Frances M. Hill, Sheila H. Hoey, Catharine E. Hollman, J. M. H. Hopper, John Houston, Edmund Howarth, T. M. Howell, D. C. Hudson, Doreen R. Hyder, Sylvia R. Ingold, Harry Jackson, R. F. Jackson, Lelia Jennings, I. M. Johnstone, Karthigesu Kanagsingam, D. P. J. Kelleher, E. I. Kohorn, Koussa Tadros Koussa, S. R. S. Laing, J. S. P. Lane, June P. Lawson, W. R. Lee, P. A. Lowe, Gwladys N. McCoach, J. Q. McCubbin, Jill Macdonald, Margaret R. MacD. McElvay, Catriona D. McLeod, R. N. Malins, C. F. R. Mallett, G. C. Mansfield, John Manuel, Patricia L. Martin, C. J. G. Menzies, Barbara I. Miller, J. S. M. Mitchelson, I. A. Moollan, Donald M. Morgan, Mavis H. Mortimer, A. L. I. Murphy, Rathindra Nath Nag, T. M. O'Brien, J. F. O'Kelly, E. G. Old, Chiew Seng Oon, Elspeth M. Orr, Margaret O'Sullivan, D. N. H. Owen, N. S. Painter, C. E. Parr, K. C. Parsons, Dina Patuok, Harrihar J. B. Pershad, William Peter, C. D. Peters, P. B. Poole, Sylvia E. Prebble, J. F. Preece, W. E. B. Preston, D. S. Ractliffe, T. F. Regan, Jean E. Ritchie, Kathleen M. Robb, T. E. Roberts, K. F. Robinson, Patricia M. Russell, Iqbal Sahney, J. F. Scarlett, Roy Schofield, Albert Schutz, F. G. M. Seager, Janet Shaw, R. G. Sinclair, G. D. Smellie, Janet U. A. Smith, S. A. Smith, Carol M. S. Spence, T. J. Stanton, Mary J. Starbuck, J. K. Steel, Michael Steele, D. H. Stewart, I. A. Stewart, W. M. B. Strangeways, Mary W. Sturges, J. S. V. Surman, Muriel M. H. Sutcliffe, W. R. Swaffield, G. S. Tapsall, M. K. Thompson, N. A. Toes, Dorothy I. Troup, A. G. Turner, Sam Vakili, M. H. Vickery, J. de M. Vink, P. O. Wakelin, Phyllis M. Wallington, D. G. Walker, A. G. Wallace, I. H. Watson, Josephine P. Werron, Susanne M. Williams, A. C. Wilson, D. G. Wilson, G. C. Winch, Hazel G. Wiseman, K. A. Wood, D. W. B. Woolven, E. G. B. Worthington, A. P. Wright, M. A. Young.

Radcliffe Infirmary

Lord Nuffield has given £15,000 to provide an operating-theatre for the Nuffield professor of surgery.

Poliomyelitis Vaccine

The National Foundation for Infantile Paralysis has given its approval for the start of the poliomyelitis vaccine trial in the U.S.A. (*Times*, April 27). The first inoculations were given to children in Virginia and Alabama on April 26.

Welfare of Handicapped Children

The National Committee for the Defence of Children is holding a conference on this subject at Church House, Westminster, on Saturday, May 8, at 2.30 P.M. Further information may be had from the secretary of the committee, Dr. Simon Yudkin, 23, Tillingbourne Gardens, London, N.3.

Varrier-Jones Lecture

Dr. Harold G. Trimble, associate professor of clinical medicine at Stanford University, California, will give this lecture at 26, Portland Place, London, W.1, on Friday, May 14, at 5 P.M. He has chosen as his subject Current Therapy in Pulmonary Tuberculosis.

Lebanon Hospital for Mental and Nervous Disorders

The annual meeting of this hospital will be held on Friday, May 7, at 5 P.M., at the Cora Hotel, Upper Woburn Place, London, W.C.1. The speakers will include Prof. Alexander Kennedy, F.R.C.P., and Dr. Alfred Torrie.

Rockefeller Grants

The grants to British organisations announced this week by the Rockefeller Foundation of New York include one of \$125,000 to the Medical Research Council for fellowships in the medical sciences. This grant assures the continuance of the M.R.C.'s programme for travelling postgraduate fellowships until 1959.

The Fever Nurse

The general-trained nurse is allowed to take her training to qualify as a fever nurse in one year instead of the usual two years. Her training allowance has been amended (N.M.C. circular no. 36), and in future she will receive for the year £335 (the usual second-year allowance) instead of £320 (the first-year allowance).

Dr. Dennis Geffen is visiting Greece, Cyprus, and Turkey on behalf of the British Council.

ARTIFICIAL RESPIRATION BY INTERMITTENT POSITIVE PRESSURE IN POLIOMYELITIS AND OTHER DISEASES

NEUROLOGIST

RADCLIFFE INFIRMARY, OXFORD

THE commonest cause of death from poliomyelitis is respiratory insufficiency. This may be due to spinal paralysis affecting the primary muscles of respiration directly, and it is in such cases that tank respirators have proved of value. In other cases "bulbar" involvement leads to paralysis of the pharynx and larynx, and there is then grave danger of pharyngeal secretions or vomit being inhaled, and causing fatal pulmonary complications. In this type of case the skilled use of postural drainage often enables unobstructed breathing to be maintained (Russell 1952).

By far the most difficult and critical problem in management is presented by the "combined case," in which the paralysis is both bulbar and spinal. Some form of artificial respiration is then essential; yet, in spite of postural drainage, the uncompromising inspiratory effort of a tank respirator leads, in the absence of the power of swallowing, to inhalation of secretions and a fatal result. In some American clinics such patients have been nursed in tank respirators, with a tracheotomy; but this method involves great difficulties, notably in establishing an airtight seal at the neck without interfering with the tracheotomy.

Recently we have treated patients with combined bulbo-spinal paralysis by artificial respiration with intermittent positive pressure (I.P.P.), a method used by Lassen (1953) during the severe epidemic in Denmark in 1952. This method has great advantages, and we describe here how four patients were treated in a small Respiratory Unit established at Oxford to deal with cases of respiratory insufficiency. Not only cases of poliomyelitis but also cases of acute toxic polyneuritis were treated, and the unit has indeed been available for the treatment of respiratory insufficiency from any cause—e.g., after head injury or neurosurgical intervention, in drug intoxication, and in tetanus.

Case-records

The following cases are the first four we have treated in this way, and we hope that this description will be helpful to other workers.

FIRST CASE

On Aug. 17, 1953, a schoolgirl, aged 16, developed a heavy cold and cough beginning with a rigor. These symptoms disappeared within twelve hours, leaving her with a sense of lassitude. This persisted, and after nine days she developed a stiff neck; but, though feeling very unwell, she played tennis in the morning and afternoon.

Ten days after the onset she remained in bed, and during the day her legs became so weak that she could not stand. In the evening she was admitted to an isolation hospital, where she was found to have considerable weakness of all limbs, especially at the proximal joints. During the night she developed dysphagia, and her voice became only a whisper. She was seen by one of us (A. C. S.) on the morning of Aug. 28 and transferred in the prone position under his supervision to the Radcliffe Infirmary.

On admission [R.I. 179909] she was alert but very apprehensive. Her temperature was 97°F, pulse-rate 82, and respirations 26 per min. She could not swallow, her voice was a hoarse whisper, and she could not close her larynx. The other cranial nerves were normal. The diaphragm was weak, but the intercostal muscles contracted satisfactorily. There was considerable generalised weakness of all the limbs, but some movement was still present at all the joints.

Treatment

She was nursed in the prone and semi-prone or "tonsil" positions, and the head of the bed was tipped down 10–15° to ensure drainage of secretions from her mouth. During the next twelve hours her condition remained substantially unchanged, but at the end of that time her *alæ nasi* and accessory muscles of respiration were working. Her blood-pressure had risen from 130/75 to 160/80 mm. Hg, and she was becoming cyanosed.

An attempt was made to treat her in the Siebe Gorman modification of the Drinker tank respirator, in which a patient can be nursed in the prone or semi-prone positions. These positions were adopted, and the head was lowered 10–15°. The pharynx was aspirated frequently, but three cyanotic attacks during the night made it plain that this régime did not provide a clear airway, and that artificial

Fig. 1—Expiratory valve, pressure gauge, McGill suction union, and cuffed tracheal tube. End of lagged breathing-tubing from humidifier is also shown.

respiration was defeating its object by causing secretions to be inhaled.

We therefore decided to establish I.P.P. respiration through a cuffed tracheotomy tube. The patient was removed from the tank respirator, and the respiration was maintained with an Oxford inflator (Macintosh and Pratt 1939) and face-mask. Bronchoscopy was performed under thiopentone anaesthesia, and the bronchi were cleared of secretions. During this procedure I.P.P. respiration from the Oxford inflator was given as required down the bronchoscope. A cuffed endotracheal tube was then passed, and with it efficient I.P.P. ventilation was maintained. This enabled a formal and unhurried tracheotomy to be done; and, as the endotracheal tube was removed, a short cuffed tracheal tube (fig. 1) was inserted through the tracheostoma.

For four weeks thereafter the patient received I.P.P. respiration from Radcliffe respiration pumps A and B (Russell and Schuster 1953) through an expiratory ("flutter") valve* (fig. 2). A humidifier (Marshall and Spalding 1953) was used

* This valve was designed by Dr. F. D. Stott as an interim measure. He is of the opinion that it can be further improved.

Fig. 2—Diagrammatic representation of mechanism of expiratory valve. Case is made of plastic, and valve of rubber.

to warm and humidify the gases to the extent which is found in the normal trachea. On the day after tracheotomy (the third since the onset of paralysis) the patient had complete paralysis of all voluntary movements throughout her body except external ocular movements.

Respiration

The respiratory exchange required was assessed by clinical judgment and by the patient's subjective reactions, which proved both sensitive and reliable. It is relatively easy to provide adequate oxygenation by the means used if there is no severe pulmonary collapse, but it is desirable to avoid over-ventilation and hence chronic respiratory alkalosis. Biochemical investigations indicate that this took place to some extent, as exemplified by the progressive rise in the pH of the urine (fig. 3).

A pressure-gauge included in the system close to the tracheal tube provided a continual visual check of pressure during inspiration and expiration.

Pulmonary Complications

Particular attention was paid to the early diagnosis of areas of pulmonary collapse. The chest was frequently examined clinically, and radiographs were taken almost daily for the first three and a half weeks. Indirect indications that some collapse had taken place were (1) anxiety on the part of the patient; (2) her dissatisfaction with a setting of the respirator which had previously satisfied her; (3) increase in the pressure shown on the gauge; or (4) increase in the pulse-rate. Direct indications of collapse were obtained by auscultation and radiography. From the fourth day after I.P.P. respiration was begun the patient received vibration and light percussion to the chest from a physiotherapist. This was done every four hours, during the acute stage; and, when any degree of collapse occurred, particular attention was directed to the lobe concerned. The trachea and bronchi were aspirated during physiotherapy, and Tiemann's catheters proved very suitable for this. If these measures failed to clear the airways bronchoscopy under thiopentone anaesthesia was performed; but with increasing experience it came to be required less and less often.

Blood-pressure

Throughout the acute stage the blood-pressure was measured half-hourly. This provided an early indication of inadequate ventilation, which causes the blood-pressure to rise promptly owing to retention of carbon dioxide. It also demonstrated the mechanism of sudden episodes of unconsciousness, which first came on during the early morning of Aug. 30, when the patient had been having I.P.P. respiration for thirteen hours. In these episodes, without warning, she became unrousable, and at the same time her blood-pressure fell from the normal level of 125/75 mm. Hg to a systolic level of 80-60 or less. Her pulse-rate, which was consistently above 90 during the first four weeks of the illness, was unchanged or fell slightly during these hypotensive attacks (fig. 4). These attacks

Fig. 3—Urinary pH in case I, showing rise to maximum of 8.3 attributable to respiratory alkalosis caused by over-ventilation.

lasted from a few minutes to a few hours; and, as soon as she became rousable, her level of consciousness returned to normal, as though she were awakening from sleep. It was impossible to correlate these attacks with any change in the artificial respiration, and they were characterised by a sudden fall in blood-pressure in contrast to the rise that is typical of under-ventilation.

Feeding

As soon as the cuffed tracheotomy tube was in place the pharynx was closed from the bronchial tree, and the possibility that the patient might vomit was no longer alarming. She was fed through a 'Polythene' stomach-tube (size 3 or 4). At first she received 4-oz. feeds hourly, comprising milk 2 oz., water 1 oz., Ringer-Fischer solution 1 oz., and two level teaspoonfuls of glucose (10 g.). No residuum could be aspirated from the stomach an hour after each feed, and twenty-four hours later an extra ounce of milk was added to each feed. On this régime an ounce or two of fluid could be aspirated occasionally, but nearly 6 pints was absorbed daily, and the specific gravity of the urine fell rapidly (fig. 5). On the seventh day of paralysis, the fluid balance having been restored to normal and absorption being good, 3 oz. of the feeds was given two-hourly, and next day were started two-hourly 8-oz. feeds of "higher protein diet no. I" (Higgins et al. 1954). The increase in dietary protein was followed by a rise in the blood-urea level (fig. 5). When this had again fallen to 40 mg. per 100 ml., "higher protein diet no. II" was begun. The patient remained on this with some additions by mouth until Sept. 25, a month after the onset, when she could be fed entirely by mouth. While she was on these diets, the electrolyte balance was maintained by varying the amount of Ringer-Fischer solution used to dilute the feeds according to the plasma-chloride level.

Fig. 4—Blood-pressure and pulse-rate in case I during first and longest hypotensive attack (on Aug. 30).

Drugs

Large doses of antibiotics were given, mainly penicillin but also aureomycin when bronchial swabs grew penicillin-resistant organisms. Sedation was produced at first with phenobarbitone and later with chloral hydrate.

Nursing

The patient was nursed on a tipping bed with its head about 10° down. She remained mainly in the two lateral positions and sometimes in the theoretically better semi-prone position. The last, however, she found very uncomfortable. She was turned every two hours throughout her illness, and the routine for turning during the acute stage was as follows: (1) the trachea and bronchi were aspirated; (2) the expiratory valve was changed; (3) the patient was turned; and (4) the trachea and bronchi were aspirated again. The act of turning often liberated a considerable amount of secretions. Every four hours, at alternate turnings, vibration and percussion were given to the chest by a physiotherapist at stages 1 and 4. At alternate turnings, when physiotherapy was not being given, the bed was tipped steeply head down, the pharynx was aspirated, and the cuff of the tracheal tube was deflated. After a minute the cuff was reinflated enough to prevent air from leaking past it, and the bed was returned to its usual tilt of 10°.

Investigations

Radiographic investigations have already been referred to. Cerebrospinal fluid (Sept. 7): no cells; protein 150 mg. per 100 ml. Electrocardiogram (Sept. 1 and Oct. 1): sinus tachycardia. Urine (twenty-four-hour specimen Oct. 5): coproporphyrin excretion less than 40 µg.; no porphobilinogen. Paul-Bunnell test (Oct. 30): negative.

Fig. 5—Fluid intake, blood-urea level, and specific gravity of urine in case 1

Progress

On Aug. 30 the patient had total paralysis of all voluntary movements except external ocular movements, and this persisted till Sept. 2, when feeble rotation of the neck became possible. Thereafter muscle power throughout the body rapidly recovered. By Sept. 21 she could breathe unassisted for thirty-five minutes, and the partial recovery of facial as well as other muscles made it easier to communicate with her. Sensory testing now showed that she had considerable loss of appreciation of posture and vibration in all her limbs, and some peripheral superficial sensory loss, considerable on the feet and slight on the hands. By Sept. 30 she could breathe unassisted. The cuffed tube was removed, and a Durham's tube was substituted. A few days later the tracheotomy was allowed to close.

She was discharged home on Nov. 18, and on March 11, 1954, her tendon reflexes were diminished, but there were no other abnormalities.

Diagnosis

In view of the profound lower motor-neurone paralysis, the peripheral sensory loss, and the large amount of protein in the c.s.f., a diagnosis of acute toxic polyneuritis was made, and her complete recovery was in accordance with this.

SECOND CASE

On Sept. 7, 1953, a schoolgirl, aged 13, developed pyrexia (100°F) and felt "a lump in her throat." Her appetite was poor, but she ate and drank at all meals. Two days later she drank about 10 oz. at breakfast with some difficulty and thereafter developed complete paralysis of swallowing. She was admitted to another hospital that evening and was found to have, besides dysphagia, weakness of the left face, the palate, the sternomastoid muscles, and the muscles of the shoulder girdles and upper arms. Anterior poliomyelitis was diagnosed.

Next morning she had a cyanotic attack which rendered her temporarily unconscious. She was lying supine at the time, and it seems likely that it was due to inhalation of secretions or of vomit, fluid being aspirated from her nasopharynx. A similar attack occurred three hours later. She was first seen by one of us (J.S.) four hours after the second attack. She did not respond to painful stimuli, and her respirations were extremely shallow and irregular at a rate of about 14 per min. She was receiving 100% oxygen through a mask, and her colour was satisfactory, but her ventilation was manifestly too small to prevent retention of carbon dioxide.

Treatment

A cuffed endotracheal tube was introduced and respiration maintained with an Oxford inflator. The patient was trans-

ferred in this way by ambulance to the Radcliffe Infirmary, a journey of some fifty minutes. During the journey she began to move her limbs and to open her eyes when told to do so.

On admission [R.I. 180349] bronchoscopy was performed, but no considerable amount of inhaled material was within reach. It was thought that when she recovered from the effects of under-ventilation she might be able to breathe spontaneously. An endotracheal tube was therefore replaced, and positive-pressure respiration was instituted down this tube from Radcliffe respiration pump A.

Next day an attempt was made to let her breathe spontaneously, but she could not. A formal tracheotomy was therefore done as in case 1, and i.p.p. respiration continued with Radcliffe respiration pump A. Two hours later, twenty-two hours after i.p.p. respiration was begun, her blood-pressure dropped to 40 mm. Hg systolic, her nail-beds and subsequently her lips became deeply cyanosed, and she died.

Investigation

Radiography of the chest on admission had showed mottled shadowing throughout the lung fields.

Necropsy Findings

The diagnosis of anterior poliomyelitis was confirmed. The endotracheal tube had been in position for twenty hours, and there was considerable ulceration of the larynx. An intense haemorrhagic consolidation involved about five-sixths of the lungs, and the relatively normal fifth was situated anteriorly. Presumably this hopeless state of the lungs was a consequence of secretions, and perhaps vomit, being inhaled on the day before death.

THIRD CASE

On Oct. 11, 1953, a schoolgirl, aged 17, developed a slight cold in the head. On Oct. 16 she noticed numbness and paræsthesiæ of both feet and the left hand. She was admitted to another hospital and three days later developed some weakness of the left upper and lower limbs and left side of the face, which was greater next day, when diplopia also developed. There was slight enlargement of the glands of the neck, a blood film showed atypical glandular-fever cells, and a positive Paul-Bunnell test subsequently confirmed the diagnosis of infective mononucleosis with the rare complication of acute toxic polyneuritis.

On Oct. 22 she had a brief cyanotic attack after vomiting, and soon afterwards developed manifest dysphagia. On Oct. 24 her intercostal muscles and diaphragm became weak and, when she was first seen by two of us that afternoon, her respirations were very shallow and she was cyanosed. Within twenty minutes the cyanosis increased, she sweated profusely, and consciousness became impaired.

Treatment

An endotracheal tube was passed, respiration was maintained with an Oxford inflator, and she quickly became alert. Under this form of positive-pressure respiration she was transferred by ambulance to the Radcliffe Infirmary, a journey of one and a quarter hours, without incident.

Fig. 6—Case 3 receiving treatment, showing Radcliffe respirator pump B, humidifier, lagged breathing-tube, expiratory valve, and pressure gauge. Patient's head is at "foot" of bed, where rail is lowest.

On admission [R.I. 182462] bronchoscopy was performed under thiopentone anaesthesia, and the bronchi were cleared of secretions. An endotracheal tube was replaced, tracheotomy was performed, and a cuffed tracheal tube was inserted. Respiration was maintained with Radcliffe respiration pump B, and subsequently respiration pump A, through a humidifier and expiratory ("flutter") valve (fig. 6).

Fig. 7—Urinary pH in case 3. Urine remained slightly acid, indicating that ventilation was not excessive.

of both lower limbs. No objective sensory loss was demonstrable at this stage, but by Oct. 29 peripheral sensory impairment to light touch was demonstrable on the hands and feet.

Respiration

The respiratory exchange was more satisfactorily controlled than in case 1, and the urinary pH showed no constant trend in either direction, remaining between 5.6 and 7.0 (fig. 7).

Since the volume of gas delivered by a pump does not satisfactorily indicate the volume of air actually ventilating the patient, we collected the expired air with a spirometer and an expiratory valve with a suitable connecting-piece on the expiratory side. The patient required 7-8 litres per min. to maintain equilibrium.

Pulmonary Complications

There were poor air entry and radiographic opacity at the left base before I.P.P. respiration was begun. Four-hourly percussion and vibration to the chest were begun at once, and the pulmonary condition never gave rise to alarm. The value of physiotherapy was well illustrated on one occasion when air entry disappeared over the left lower lobe. Percussion and vibration enabled a plug of mucus to be aspirated with a Tiemann's catheter, and air entry was immediately restored.

Blood-pressure

No hypotensive attacks occurred. The blood-pressure was usually about 100/55 mm. Hg. On her first day the patient was receiving respiration at 5.6 litres per min., and her blood-pressure gradually rose, indicating under-ventilation, and settled again when respiration was increased to 8 litres per min. (fig. 8).

Feeding, Drugs, and Nursing

In feeding, the same principles were followed as in case 1. Milk, water, and glucose were given for the first day and a half; and thereafter, since the blood-urea level was normal and fluid was well absorbed from the intestine, "higher protein diet no. 1" was begun. The resulting rise in blood-urea to 56 mg. per 100 ml. settled within two days, and six days after her admission to this hospital she began to receive "higher protein diet no. II."

Fig. 8—Blood-pressure in case 3, beginning 6 hours after I.P.P. respiration was begun. At arrow, ventilation was increased from 5.6 to 8 litres per min.

She received penicillin and chloral hydrate. A course of aureomycin was stopped after two days, owing to a mild toxic reaction.

The same nursing routine was applied as in case 1.

Progress

On the fifth day after I.P.P. respiration was begun the first signs of recovery were observed. She could make a few feeble respiratory movements, and there was a little recovery of the cranial nerves and the right deltoid muscle. Muscle power recovered quickly, with the result that on Nov. 3 she could breathe spontaneously for ten minutes. By Nov. 10 she required no respiratory assistance, the tracheal tube was removed, and the tracheostoma was allowed to close. There was still impaired sensation of light touch and pinprick in a "glove-and-stocking" distribution in all her limbs and considerable impairment of vibration sense and appreciation of passive movement in the lower limbs. By Dec. 9 she was walking about, and the only abnormalities were slight weakness of the left shoulder and hand, the pelvic girdle, and quadriceps muscles. Complete recovery took place later.

FOURTH CASE

A well-built man, aged 32, developed a headache on Nov. 5, 1953, and next day complained of weakness of his right arm. During the next night he had dysphagia and respiratory difficulty. He was first seen by two of us next morning, when he was breathing with difficulty and became cyanosed on the slightest exertion. His pharynx contained a pool of secretion, and there was no air entry over the left lower lobe. There

Fig. 9—Urinary pH in case 4. Initial rise is due to rehydration of patient. Thereafter pH remains slightly acid, indicating that ventilation is not excessive.

was very little movement of the left chest, and paradoxical movement on the right side indicated that the right diaphragm was functioning but the right intercostals were not. There was generalised weakness of the right upper limb, less marked weakness of the left upper limb, and a moderate weakness of both lower limbs. The ankle-jerks were the only tendon reflexes obtainable. There was no sensory loss. The c.s.f. (examined elsewhere) contained protein 95 mg. per 100 ml. and 405 cells per c.mm. (lymphocytes 347, polymorphs 45, macrophages 12). A diagnosis of anterior poliomyelitis was made.

Treatment

He was transferred to the Radcliffe Infirmary by ambulance under the supervision of one of us (A. C. S.)—a journey of thirty-five minutes. An endotracheal tube was not passed, but apparatus for intubation and I.P.P. respiration was available in the ambulance.

On admission [R.I. 183157] bronchoscopy was performed under thiopentone anaesthesia with succinylcholine iodide, and a considerable quantity of secretions was removed from the bronchi. An endotracheal tube was then passed, a tracheotomy was done, and I.P.P. respiration established with Radcliffe respiration pump A through a humidifier and expiratory valve as in the previous cases.

Next day the paralysis of the limbs had increased considerably. A trace of movement persisted in the right diaphragm, but the vital capacity was only 200 ml.

Respiration

This patient was known to have a psychopathic personality with hysterical features, and his subjective sensations were worse than useless as a guide to adequate ventilation, because he contradicted himself. For the first fourteen hours he received ventilation of 7.5 litres per min. This was thought insufficient in view of an estimated partial pressure of carbon dioxide in capillary blood of 60 mm. Hg, and the ventilation was increased to 9.8 litres per min. Thereafter he continued to receive about 10 litres per min, and this kept him almost

Fig. 10—Case 4: a, on admission; b, 5 days later, showing resolution of severe abnormalities on left side.

in respiratory equilibrium, judged by his blood chemistry and urinary pH (fig. 9).

Pulmonary Complications

The abnormalities at the left base, which were considerable when he was first seen, cleared up with routine physiotherapy and suction, and no serious pulmonary complication developed (fig. 10).

Blood-pressure

There were no hypotensive attacks. For the first week the patient's blood-pressure remained about 110/60 mm. Hg, but thereafter it began to rise very gradually; two weeks later it was between 140/100 and 200/130. The ventilation was increased from 10 litres to 13 litres per min. for twelve hours, and this produced biochemical evidence of hyperventilation but did not lower the blood-pressure. The hypertension gradually diminished, and two months after the onset the blood-pressure was 130/80.

The patient's psychiatric abnormalities made it difficult at times to interpret changes in blood-pressure. For instance, when he was being weaned from artificial respiration, his blood-pressure used to rise sharply as soon as the pump was turned off. Within half an hour it returned to its previous level and he would often fall asleep. Clearly this hypertension was psychogenic, and not the result of carbon-dioxide retention.

Feeding, Drugs, and Nursing

The same principles were applied as in cases 1 and 3.

Progress.—By Nov. 28 he could breathe spontaneously for five and a half hours out of the twenty-four and by Dec. 28 he could breathe unassisted by day and night.

Discussion

The method of artificial respiration used for these patients has three great advantages: first, a cuffed tube inserted through a tracheotomy wound separates the pharynx from the trachea so that there is no danger of inhalation of foreign material even if the patient vomits; second, it permits secretions to be aspirated readily from the trachea and bronchi; third, it provides a route for artificial respiration by I.P.P. with the attendant advantages, compared with respiration in a tank, of ready access to the patient and of low cost of apparatus.

Patients with paralysis causing respiratory embarrassment are critically ill, but, as illustrated above, if they survive, even those with both bulbar and spinal involvement may make an excellent recovery. Their treatment is a specialised matter and presents many problems which are not commonly met with in other branches of medicine. It is therefore best carried out in a special unit whose doctors and (very important) whose nurses are experienced in treating this type of case. A considerable staff of doctors and nurses is required to give adequate treatment in the acute stage; and, since the number of cases requiring treatment, and therefore the number of staff required, varies greatly from time to time, a unit that is to treat such cases is most conveniently situated in a large hospital which can support a drain on its resources. Moreover it is in large hospitals that the ancillary services required are available.

This recommendation is in accordance with the policy put forward by the Royal College of Physicians (1953) and the Ministry of Health (1953). Whether the unit should be situated at a general hospital or a hospital for infectious diseases depends on local conditions.

TRANSPORT

A patient with paralysis may develop respiratory embarrassment with little warning, and this may happen when the patient is at home or in a hospital which has neither the equipment nor the organisation to deal with this condition. This fact has in the past militated against the formation of special units for these patients, but it now appears that it is relatively simple to transport them. Any unit intending to treat cases of this type must be prepared to send out a team, consisting of an anaesthetist and a physician, to provide for the safe transport of the patient. This team must be prepared to intubate the trachea with a cuffed endotracheal tube under either local or general anaesthesia, and to provide a portable source of I.P.P. respiration and of suction. The Oxford sucker-inflator unit (supplied by M.I.E. Ltd., 12, New Cavendish Street, London, W.1) has proved very suitable for this purpose. The requisite equipment can be carried in any car and should be kept ready for immediate use. It will often be unnecessary to intubate the patient for transport, as in cases 1 and 4, but it is nevertheless essential for the anaesthetist to travel with the patient in the ambulance and to be prepared to intubate if necessary.

For transport, we prefer intubation through the mouth to tracheotomy, since it enables the patient's condition and therefore the need for tracheotomy to be reassessed after a period of satisfactory ventilation. Moreover, if tracheotomy is required, a formal and unhurried operation can most easily be performed in the respiratory unit by a surgeon experienced in this operation. Tracheotomy must not, however, be unnecessarily delayed, owing to the danger of ulceration of the larynx if an endotracheal tube is left in situ for even a few hours.

I.P.P. RESPIRATION

The circuit used was an open circuit with no rebreathing, and it supplied air 100% saturated with water vapour at 36°C. Additional oxygen was sometimes used. We attempted to maintain a ventilation-rate appropriate to the patient's need without excessive inspiratory pressures. During the expiratory phase tracheal pressure was atmospheric, and expiration slightly exceeded inspiration in length.

Respirators

To provide I.P.P. respiration Lassen (1953) used a semi-closed system and relied on students to squeeze an anaesthetic bag supplied from cylinders containing oxygen and nitrogen. We have used Radcliffe respiration pumps A and B (made by H. G. East & Co., Longworth Road, Oxford) (Russell and Schuster 1953) to supply positive pressure. These pumps are easy to adjust to the patient's needs, and eliminate any risk of accidental overdistension of the lungs. They give a rapid rise in pressure at the beginning of inspiration

Fig. 11—Pressure record at trachea taken with a condenser manometer, with Radcliffe respiration pump A at 20 respirations a minute. Rapid rise in pressure at start (arrow) of inspiration is a feature of this pump.

(fig. 11), which ensures that the lungs are well filled for the greater part of inspiration. Maloney et al. (1953) advocate a machine which provides negative pressure during expiration. We have not had the opportunity of testing such a machine, but there is need for further study of the effects of different pressures and rates of change of pressure during both expiration and inspiration. Unfortunately the records illustrated by these workers show that this machine was compared with another which permitted only gradual expiration and with which the expiratory pressure did not fall below 5 cm. water.

Though oxygen or any other gas can be delivered by Radcliffe respiration pumps they normally use room air, which possesses the great advantage of being readily available. Lassen (1953) has described the difficulties and expense of maintaining a supply of gas cylinders when he used hand-operated I.P.P. respiration. The same problem arises in respiratory machines (Bang 1953, Macrae et al. 1953, Pask 1953) which rely for their motive power on the pressure from a cylinder of compressed gas.

Humidifier

The value of humidification to keep secretions fluid has been emphasised by Lassen (1953). It is physically impossible to produce humidification that in any way simulates that obtaining in the normal trachea, unless the humidifier also warms the air and is placed between the respirator and the patient. The simple apparatus described by Marshall and Spalding (1953) has proved satisfactory. When it has been in use, secretions have remained moist and were readily removed by aspiration. When the patients were being weaned from the respirator and were breathing spontaneously through the tracheal tube, sticky secretions sometimes occurred, and the patients complained of discomfort and difficulty in breathing, which was relieved by further humidification. To obviate this a plastic bag was placed loosely over the free end of the tracheal tube, and the pump was used to blow humidified air into it. This device enabled the patient to breathe warm humidified air mixed with room air and has facilitated the weaning phase.

Expiratory Valve

The most important feature of an expiratory valve is that it should permit perfectly free expiration; for, if the tracheal pressure does not fall to atmospheric in expiration, there is a deleterious effect on the circulation (Werkö 1947, Cournand et al. 1948, Motley et al. 1948). For this reason any form of expiratory apparatus which depends for its proper functioning on introducing resistance cannot be regarded as satisfactory. The "flutter" valve (made by Owen Mumford & Co. Green Place, Abingdon Road, Oxford) used in these cases has proved adequate. To ensure rapid opening of this type of valve to the expiratory position negative pressure from the respirator is necessary, and a non-return valve on the delivery side of the respirator must therefore not be used.

Pressure Gauge

The use of a pressure gauge (made by K. D. G. Instruments Ltd., Purley Way, Croydon) close to the tracheostoma has proved of special value because it provides a continual visual check on the working of the I.P.P. system. It shows that in inspiration the maximum safe intrapulmonary pressure is not being exceeded, and in our experience pressures above 20 cm. water are rarely required. It also gives positive evidence that the expiratory valve is opening freely. Moreover a change in the readings gives an early indication that something is wrong. A rise in pressure suggests pulmonary complications, and a fall a leak in the system, either outside the patient or beside the tracheal cuff. In either case early treatment will avoid serious mishaps.

Tracheal Tube

We have used cuffed endotracheal tubes cut to a length of about 4½ in. At the external end a McGill suction union is connected, and through the opening in this, which is normally kept occluded, aspiration can readily be applied. The lower end of the tube is also cut short immediately below the cuff, with the minimum of bevel, for this end reaches almost to the carina and, if too long, can easily enter the right bronchus, occluding the left. For the same reason tracheotomy should be as high as possible. The cuff is deflated briefly every four hours to protect the tracheal mucosa, and a fresh tube is inserted every three or four days.

Ventilation

The dangers of inadequate ventilation with hypoxia and retention of carbon dioxide are well recognised. Those of over-ventilation are not at present well defined. There are extremely sensitive mechanisms in the normal person which prevent over-ventilation, and if it occurs it produces profound alterations in body electrolytes. It therefore seems highly unwise to induce over-ventilation in a sick person, whose ability to compensate may be impaired or who may not be in a condition to withstand a change in ionic balance. The importance of maintaining electrolyte equilibrium has been increasingly appreciated in recent years in other serious conditions—e.g., diabetic coma, the postoperative state, and severe injury—and should not be neglected in this instance.

It is not easy to assess when adequate ventilation is being provided, and the patient's subjective sensations, often a most useful guide, are not available in the most difficult instances—i.e., in the acute stage, when the patient may be unconscious or incapable of cooperation, and in children. Objective criteria are therefore desirable.

We have measured in a spirometer the volume of air expired each minute, and have found this a valuable procedure. Cases 1 and 3, girls aged 16 and 17, of slight build, required 7-8 litres per minute, whereas case 4, a heavily built labourer, required about 10 litres per minute. In all the cases the respiratory rate was 16-20 per minute. A minute volume that is approximately correct can thus be assured, and it can be adjusted in the light of the patient's progress. Slight under-ventilation can be detected by a gradual rise in blood-pressure, and over-ventilation by a rise in the urinary pH. The conclusions drawn from these estimations may be confirmed by investigating the blood chemistry.

Pulmonary Complications

Patients with bulbo-spinal paralysis are extremely liable to pulmonary complications since they cannot cough and rid themselves of their secretions. Prophylaxis and early treatment are essential, and the following prophylactic measures have been adopted.

(1) Two-hourly changes of posture from one side to the other; these often loosen secretions so that they can be easily aspirated.

(2) Four-hourly vibration and percussion by a physiotherapist; these to a considerable extent took the place of the normal cough in removing secretions.

(3) Aspiration of trachea and bronchi with Tiemann's catheter, whenever secretions are present. This catheter is rather stiff and has a curved tip by which it is possible, with the patient lying on, say, the right side, to pass the catheter into the bronchi of the left (uppermost) lung which is receiving physiotherapy.

(4) Hydration of the patient and humidification of the inspired air. In this way the secretions are kept fluid and easy to aspirate.

(5) Antibiotic therapy.

In the presence of established pulmonary collapse these measures were intensified. If they failed, bronchoscopy was performed, but the need for this became less and less frequent as experience was gained.

Although bronchoscopy through the tracheostoma is easy, it proved impossible to ventilate an apnoeic patient adequately through a bronchoscope in this situation, because of leaks round the instrument. Bronchoscopy was therefore performed through the mouth, with the tracheostoma temporarily occluded. Thiopentone anaesthesia, with or without relaxants and with intermittent inflation with oxygen, proved satisfactory.

BLOOD-PRESSURE

Lassen (1953) found frequent records of the blood-pressure a useful guide to correct ventilation, since carbon-dioxide retention is quickly reflected in a rise in blood-pressure. Although in some circumstances the significance of changes in blood-pressure was sometimes difficult to determine, in most instances valuable information was obtained from half-hourly records.

FEEDING, DRUGS, AND NURSING

Feeding.—With a cuffed tube in the trachea the bronchial tree is separated from the pharynx, and the dangers and deficiencies of parenteral nourishment, which may have to be faced in some cases of dysphagia without respiratory weakness, can be avoided. Polythene nasal tubes are less irritating than rubber and require changing less frequently. In an illness of the severity and duration of most cases of bulbo-spinal paralysis it is important that nourishment be adequate. Not only must the intake of fluid and calories be satisfactory, but also the diet should be mixed and contain as much protein as can be metabolised, judged by the blood-urea level. We have used the diets described by Higgins et al. (1954), which provide 2200 calories or more daily. They were diluted with water or with Ringer-Fischer's solution as biochemical investigations indicated.

Drugs.—Antibiotics are required in full doses. Sedation is necessary, especially in the early stages, and chloral hydrate and phenobarbitone have both been used.

Nursing.—A severely paralysed patient requires a great deal of careful nursing, and I.P.P. respiration allows completely free access to the patient, in striking contrast to artificial respiration in a tank respirator. Patients must be nursed on a bed that can be easily tipped. They will often be slightly head down, and therefore care of the skin over the acromioclavicular joint is especially important. Since it is not one of the classical pressure areas it is liable to be overlooked.

At least two nurses are required to turn a badly paralysed patient, and during the acute stage it has been our practice to have a doctor attending to respiration during turning, and readily available at all times.

Summary

"Combined" paralysis of both the pharynx and the muscles of respiration presents a very difficult problem in treatment, for which careful preparation is desirable.

This requires the organisation of small units in a well staffed hospital, members of which are prepared to act as a mobile team to transport patients safely under conditions of full control of respiration. The transport of such patients is usually safe even when they are completely paralysed.

The method introduced by Lassen (1953) of artificial respiration by intermittent positive pressure via a cuffed tracheotomy has been found satisfactory, and four cases are described.

This method with respiration pumps now available promises to be the method of choice in the treatment of this most critical group of cases.

We are specially indebted to Mr. R. G. Macbeth, director of the department of otorhinolaryngology, Radcliffe Infirmary, for his assistance in the development of this unit. In addition, we were most dependent on expert assistance unstintingly provided by many anaesthetists, E.N.T. surgeons, biochemists, physicians, physiotherapists,

and nurses, at all hours of the day and night. Dr. G. S. Dawes kindly took the pressure record in fig. 11.

SIDE-EFFECTS OF OXYTETRACYCLINE THERAPY

PETER HAY

M.B. Glasg.

MEDICAL REGISTRAR

PETER MCKENZIE

M.B. Glasg., D.P.H.

CONSULTANT PHYSICIAN

BELVIDERE INFECTIOUS DISEASES HOSPITAL, GLASGOW

OXYTETRACYCLINE (tetracycline) has been used in this hospital to treat gastro-intestinal infections and other susceptible infections when another antibiotic has been unsuccessful. The dosage given to children was 20 mg. per kg. of body-weight daily in four equal divided doses. The course lasted five days in every case except where the oxytetracycline was discontinued owing to side-effects. The dose given to patients aged 12 years or more was 2 g. daily, and this was the largest dosage used. The oxytetracycline was given with copious fluids, usually milk. Vitamin-B supplements were also given.

Not unnaturally side-effects were observed in some cases, showing once more that antibiotics upset the complex host-parasite-drug relationship, of which we know relatively little.

Most reports on oxytetracycline toxicity refer to nausea, vomiting, heartburn, diarrhoea, and headache as the most common manifestations; but we decided not to include these symptoms per se, because in most cases it was difficult to determine whether such symptoms were signs of the initial disease or of drug disturbance. Another reason is that many of our patients were infants and therefore unable to complain of minor symptoms. 2 cases of acute gastro-enteritis are included, however, for reasons that will be made clear below. Also, patients exhibiting other syndromes have had concomitant vomiting and diarrhoea.

The clinical syndromes observed during the treatment of 603 patients with oxytetracycline in the fourteen months from October, 1952, to December, 1953, are shown in table 1.

Illustrative Case-histories

SYNDROMES ASSOCIATED WITH COAGULASE-POSITIVE

Staphylococcus aureus

Group I: Fulminating Gastro-enterocolitis

Case 1.—A girl, aged 6 years, was admitted as a carrier of *Salmonella typhimurium*. She was physically well. On the fourth day of oxytetracycline administration she developed

TABLE I—CLINICAL SYNDROMES DEVELOPING DURING OXYTETRACYCLINE THERAPY

Group	No. of cases	<i>Staph. aureus</i>	
		Isolated	Not isolated
I: fulminating gastro-enterocolitis ..	2	1	1
II: sore throat			
With rash—i.e., staphylococcal scarlet-fever syndrome ..	7	6	1
Without rash ..	8	3	5
III: no throat lesion			
With rash—i.e., "surgical" or extrafacial staphylococcal scarlet-fever syndrome ..	1	1	0
Without rash ..	3	3	0
Totals of groups I-III ..	21	14	7
Group IV: pyrexia as sole clinical feature ..	24	0	24
Group V: urticaria ..	3	0	3
Group VI: transient erythema ..	4	0	4
Totals of groups IV-VI ..	31	0	31

a pyrexia of 99°F, with a little vomiting and green diarrhoea. On examination she had inflamed fauces, with white patches of exudate. Oxytetracycline was discontinued. That day the pyrexia increased to 102°F. The child had twelve loose stools in twenty-four hours, but she developed intense peripheral circulatory failure next morning and died twenty-four hours after onset of diarrhoea.

Necropsy findings.—Patchy areas of early inflammation were seen in the stomach, duodenum, jejunum, ileum, caecum, ascending colon, and descending colon. The appearances did not indicate gross damage. The stools contained a considerable amount of mucus and were pea-green. No significant abnormality was found in any of the other systems.

Bacteriology.—Cultures made from the throat and faeces on the fourth day of therapy produced a pure growth of coagulase-positive *Staph. aureus*. Post-mortem cultures from all levels of the intestinal tract and the lungs produced a pure growth of coagulase-positive *Staph. aureus*, which was resistant to penicillin, aureomycin, and oxytetracycline, and sensitive to chloramphenicol and streptomycin.

Case 2.—A boy, aged 2 years, was admitted with a clinical diagnosis of dysentery; there was a week's history of greenish diarrhoea with mucus but no blood. He had been vomiting intermittently. His sister was known to have Sonne dysentery. Physically there was no abnormality of note. His stool cultures showed no intestinal pathogens. He had two loose stools a day until the early hours of the fifth day of treatment with oxytetracycline, when he suddenly developed profuse vomiting and diarrhoea. He had nine loose stools before 8 A.M. Signs of peripheral circulatory failure became evident, and intravenous fluids were given immediately. His watery stools continued throughout the day, but his condition deteriorated and he developed a pyrexia of 104.2°F. He died at 4 A.M. on the sixth day, just twenty-six hours after the acute onset of symptoms.

Necropsy findings.—Numerous small mucosal hæmorrhages were present in the stomach. The Peyer's patches of the

ileum were swollen, many being congested. The intervening mucosa showed no abnormality. The large bowel showed nothing of note. No significant abnormality was found in any of the other systems.

Bacteriology.—No pathogens were isolated ante-mortem from rectal swabs. Post-mortem cultures from bowel showed no dysenteric, salmonella, or coliform organisms. No attempt was made to isolate *Staph. aureus* because we did not suspect this organism at that time.

Although *Staph. aureus* was not isolated from this case, we think that the similarity between this case and case 1 is such that the aetiology was probably the same in both cases.

Group II: Sore Throat

(1) **With rash.**—7 patients developed a scarlatiniform rash with throat lesions on the fourth or the fifth day of treatment with oxytetracycline, and 5 of them had severe diarrhoea simultaneously. In 6 cases a pure growth of coagulase-positive *Staph. aureus* was obtained from throat swabs (table II). The following are illustrative examples:

Case 5.—A girl, aged 2 years, was admitted with a *Salmonella enteritidis* infection of the gastro-intestinal tract. On her fourth day of treatment she developed a pyrexia of 100.6°F, her fauces being much injected. A day later her fauces were cedematous, with areas of white ulceration. She had severe diarrhoea. Oxytetracycline was discontinued. Next day her fauces and buccal mucosa were much injected, with a white glazy film over them; the ulceration of the fauces persisted, and punctate erythema appeared. The child's persistent diarrhoea had produced dehydration, which was aggravated by her inability to swallow, because of her sore throat. She was treated with intravenous fluids, intravenous sulphadiazine 1 g. four-hourly, and intramuscular antistreptococcal serum 10,000 units. The day after treatment was started the rash was fading, but the white film on the fauces and buccal mucosa had extended on to the palate. Next day the rash disappeared; but there was extensive white ulceration of the palate and fauces, although the initial fiery redness of the surrounding mucosa was subsiding. The temperature came down to normal and remained so. (The pyrexia had persisted for five days, lasting two days after the start of sulphadiazine therapy.) The diarrhoea also lessened. Since the child had been rehydrated and could swallow fluids, the intravenous therapy was terminated after four days. The white ulcerated oropharyngeal lesions steadily improved till healing was complete on the seventeenth day after the start of treatment, leaving evidence of uvular scarring.

Bacteriology.—Throat swabs on the fourth day after the start of treatment produced a pure growth of coagulase-positive hæmolytic *Staph. aureus* resistant to penicillin, aureomycin, and oxytetracycline, and sensitive to chloramphenicol and streptomycin. Cultures made from the throat, sputum, and a sore on the tongue produced a pure growth of this organism for eight days after the initial pyrexia. *Staph. aureus* was not isolated from the faeces. Attempts to find candida in the oropharynx and faeces were unsuccessful.

T.C., throat culture. U.C., urine culture.

Case 6.—A girl, aged 3 years, sister of case 5, presented a similar clinical picture with similar bacteriological findings.

Case 7.—A girl, aged 3 1/2 years, was admitted with Sonne dysentery. On the fourth day of oxytetracycline therapy she developed pyrexia (99°F), with vomiting and diarrhoea. A macular erythema appeared which became a generalised punctate erythema. Intense petechial congestion of the pharynx and rhagades of the lips were present. The oxytetracycline was discontinued. Next day the rash was not so intense. The child had occasional bouts of vomiting but was not dehydrated. The pharyngeal congestion had extended forwards on to the palate and buccal mucosa. The following day the oropharyngeal congestion persisted, and there were white glazy patches of exudate on the anterior pillar of the fauces and on the palate. The vomiting and diarrhoea ceased. More exudate developed in the pharynx in the next twenty-four hours when the last remnants of the rash were seen. The throat exudate persisted for nine more days before clearing. During this time the lips became ulcerated, especially at the angles of the mouth.

Bacteriology.—Throat culture on the first day of the throat infection produced a profuse pure growth of hæmolytic coagulase-positive *Staph. aureus* resistant to penicillin, aureomycin, and oxytetracycline, and sensitive to chloramphenicol and streptomycin. A pure growth was obtainable from the throat for five days, and the staphylococcus was the predominant organism in the throat for seventeen days. *Staph. aureus* was not cultured from the faeces. A search for candida in throat and faeces was unsuccessful. A skin test for sensitivity to oxytetracycline was negative.

The following was a presumptive case :

Case 8 developed pyrexia, injected throat, and generalised punctate erythema on the fourth day of treatment. No bacteriological examination was made in this patient, but the clinical features and time of onset indicate that the aetiology was probably the same as in the cases already mentioned.

(2) *Without rash.*—A febrile disturbance with infection of the oropharynx developed in 8 patients on the fourth or the fifth day of treatment (apart from case 17), and in 3 of them a coagulase-positive *Staph. aureus* was isolated as a pure growth on throat culture (table III).

Case 10.—A girl, aged 5 years, with Sonne dysentery developed pyrexia (100-2°F) and had enlarged and inflamed tonsils and uvula on the fourth day of treatment.

Bacteriology.—Throat culture produced a pure growth of *Staph. aureus* sensitive to chloramphenicol and resistant to penicillin, aureomycin, oxytetracycline, and streptomycin.

This patient had another course of oxytetracycline later with no untoward effect, the staphylococcus having been eliminated.

Case 11.—A boy, aged 5 years, with Sonne dysentery developed pyrexia (100-2°F), vomiting, and diarrhoea on the

fifth day of treatment. His pharynx and tonsils were red. His pyrexia settled in twenty-four hours, but his throat did not clear for four days.

Bacteriology.—Throat culture produced a pure growth of coagulase-positive *Staph. aureus* resistant to penicillin, aureomycin, oxytetracycline, and chloramphenicol, and sensitive to streptomycin.

Case 12.—A girl, aged 3 years, sister of case 1, developed pyrexia (102°F) on the fourth day of treatment with oxytetracycline. She had neither vomiting nor diarrhoea, but she had an intensely inflamed throat, with white glazy patches of exudate. The pyrexia settled in forty-eight hours, and the throat cleared in four days.

Bacteriology.—Throat culture produced a pure growth of coagulase-positive *Staph. aureus* resistant to penicillin, aureomycin, and oxytetracycline, and sensitive to chloramphenicol and streptomycin.

The 5 patients in whom no bacteriological examination was made are presumed to have had a similar infection to that in the 3 described because they had a remarkably similar time of onset, and clinically they presented an indistinguishable picture.

Group III : No Throat Lesion

(1) *With rash.*—Case 18 presented as a scarlatiniform syndrome of extrafaucial or "surgical" scarlet-fever type, his infective lesion being a balanitis from which a pure growth of coagulase-positive *Staph. aureus* resistant to oxytetracycline was isolated.

(2) *Without rash.*—3 patients developed urinary infections due to a coagulase-positive *Staph. aureus* resistant to oxytetracycline. One of them (case 21) required a further course of oxytetracycline after the urinary infection was treated, and had no upset during this second course (table III).

SYNDROMES NOT ASSOCIATED WITH COAGULASE-POSITIVE *Staph. aureus*

Group IV : Pyrexia

24 patients developed pyrexia (at least 99°F) without other signs or symptoms during treatment with oxytetracycline. The remarkable feature about these cases was the similarity of the time of onset: they all occurred from the third to the sixth day (20 of them on either the fourth or the fifth day) after the start of oxytetracycline therapy (table IV). The coincidence of the time of onset of pyrexia with time of onset of the staphylococcal lesions reported above suggests a similar aetiology. No definite clinical sign apart from pyrexia was observed in these patients, and no bacteriological examinations

cycline, and proceeded to ulcerative stomatitis, pharyngitis, diarrhoea and vomiting. This case corresponds closely to those we report here. The second case is stated to have developed the same signs and symptoms on the ninth day of aureomycin therapy.

The syndrome appears to consist of fever, throat lesions (sometimes very severe), scarlatiniform rash, and (in 5 of our cases) concomitant vomiting and diarrhoea. However, we think this infection is analogous to the modern concept of hæmolytic streptococcal scarlet fever, in which may be found infectious sore-throat syndromes, and the erythema only appears if the patient is sensitive to the erythrogenic toxins. Case 18 appears to be an example of extrafaucal or "surgical" scarlatina with the balanitis as the site of infection. This case occurred on the seventh day after the start of oxytetracycline therapy; but, as several of our cases show, *Staph. aureus* may persist in a pure culture from an infected site for several days after the cessation of treatment.

Seven of the throat infections (cases 1, 3, 5, 6, 7, 9, and 12) had intense congestion of the fauces and buccal mucosa and white glazy patches of exudate, which resembled moniliasis. In view of published reports suggesting that moniliasis might complicate the use of broad-spectrum antibiotics (Harris 1950, Woods et al. 1951, Tomaszewski 1951, and others), attempts were made to find candida in the mouth, throat, and rectum by culture on Sabouraud's medium but without success. In these cases a pure growth of *Staph. aureus* alone was obtained from the oropharynx.

Vomiting and diarrhoea were additional signs in 6 cases to other symptom complexes, but in 2 cases vomiting and diarrhoea on the fourth and the fifth days after the start of oxytetracycline therapy led to the death of the children within a very short period from the onset of these signs, in spite of intravenous fluids and anti-shock treatment. In only 1 of them (case 1) did we isolate *Staph. aureus* from the bowel.

Reports from many workers indicate that staphylococcal gastro-enterocolitis is a serious complicating factor in antibiotic therapy, particularly during therapy with oxytetracycline (Jackson et al. 1951, Janbon et al. 1952, Terplan et al. 1953, Dearing and Heilman 1953, Fairlie and Kendall 1953, Gardner 1953). These cases occur both with and without the finding of a *Staph. aureus*; and pathologically some are described as having pseudo-membranous ileocolitis, whereas others show no disturbance of the mucosa. Little abnormality was noted in the mucosa of case 2, but case 1 showed patchy areas of early inflammation throughout the gastro-intestinal mucosa and watery pea-green stools. Many workers suggest that the sudden onset, dramatic progress, and clinical features of this gastro-enterocolitis resemble

were made; so we cannot attribute the pyrexia to any known cause. The investigation of these cases was mainly retrospective, which fact explains the lack of bacteriological examinations made to find an aetiological agent. The time of onset of the pyrexia was earlier than would be expected if the pyrexia was due to drug allergy. A similar number of cases of gastro-intestinal infections treated with other drugs were surveyed, but no evidence of pyrexia on the fourth or the fifth day was found.

Group V: Urticaria

3 patients (table v) developed urticarial lesions in association with oxytetracycline therapy. One of them (case 15) had had a throat infection on the fourth day of treatment. Another (case 47) exhibited the appearances of serum-sickness, with massive urticaria, circumoral and circumorbital oedema, and pains in his joints.

Group VI: Transient Erythema

A transient erythema was seen in 4 patients (table v); it came on from the eighth to the tenth day after the start of oxytetracycline therapy. In 3 of these cases throat cultures were made, but no organisms were isolated.

Discussion

In this series of 603 patients side-effects other than mild gastro-intestinal upsets developed in 51 patients on 52 occasions. This represents an incidence of about 8%.

The scarlet-fever syndrome observed in 8 cases is of interest because *Staph. aureus* was the only organism isolated in 7 of them. Staphylococcal scarlet fever is not unknown and has been described by several workers. Aranow and Wood (1942) reviewed the published reports on staphylococcal scarlet fever and made reference to the isolation of the erythrogenic toxin. We have found 6 published cases of this syndrome complicating antibiotic therapy.

Finland (1951) cites Chang and Jackson as having noted it in 3 patients under treatment for either pertussis or diphtheria with some of the newer antibiotics (unspecified), and stating that the rapid disappearance of *Haemophilus pertussis* and *Corynebacterium diphtheriae* from nasopharyngeal cultures was promptly followed by the development of typical scarlet fever, pharyngeal swabs showing pure cultures of hæmolytic *Staph. aureus* and no hæmolytic streptococci. Finland mentions another case of staphylococcal scarlet fever in a patient receiving prophylactic penicillin for an extensive burn, the organism being cultured from the throat and the surface burn.

Hazen et al. (1951) record 2 cases. In one a scarlatiniform rash developed on the third day of therapy with oxytetra-

Asiatic cholera, and Janbon et al. (1952) call this syndrome *le syndrome cholérique de la terramycine*.

The pathogenesis of these conditions is not yet clear. At present most workers consider that the resistant staphylococci become pathogenic when the other organisms are suppressed by broad-spectrum antibiotics or by the combination of penicillin and streptomycin. The view has been advanced that these drugs might actually stimulate the organisms to pathogenicity or to the production of toxins (Fairlie and Kendall 1953, Prissick 1953). Fairlie and Kendall support this view because some of their patients exhibited symptoms as early as twenty-four hours after antibiotics were first given. However, in our cases, where a resistant staphylococcus was involved, the onset was usually on the fourth or fifth day after the start of antibiotic therapy. Since Linsell and Fletcher (1950) and Di Caprio and Rantz (1950) found that the normal flora present before therapy was either eliminated or much reduced shortly after the start of therapy (Linsell and Fletcher stated that coliform bacilli and faecal streptococci were entirely eliminated in all of their cases by the third day), we are of the opinion that the staphylococci isolated in our cases became pathogenic after the normal flora had been suppressed. The gastro-intestinal upsets observed suggest that the staphylococci might secrete an enterotoxin similar to, or the same as, that observed in food-poisoning due to staphylococcal enterotoxin. This well-known syndrome is clinically similar to the staphylococcal gastro-enterocolitis we describe.

Hofer and McCaskey (1954) summarised the many mechanisms which may play a part in an antibiotic-resistant "superinfection" into three groups: (1) environmental factors (e.g., where suppression of sensitive organisms upsets possible symbiotic states); (2) stimulation of bacterial growth by antibiotics; and (3) tissue alterations. Under this last heading they point out that aureomycin, oxytetracycline, and chloramphenicol may cause clinical vitamin deficiency. They suggest that the alteration of the bowel flora resulting in vitamin-B deficiency may also favour acute enterocolitis as a result of local tissue alteration and, perhaps, decreased body resistance.

3 of our patients developed urinary infections due to resistant staphylococci; these cleared up on therapy with antibiotics to which the staphylococci were sensitive. The predominance of this organism in the urine after the use of oxytetracycline has been noted by other workers (Finland et al. 1950, Jackson et al. 1951, Womack et al. 1952).

It will be observed that the 5 cases in which phage-typing was done indicate that three different organisms were involved. Indeed, cases 1 and 12, sisters who were admitted together and who developed side-effects on the same day, acquired their "superinfections" from two different phage-pattern strains.

We suggest that the organism was probably harboured by the patients on admission, because these cases occurred in different wards, at different times, and with different nurses. On two occasions 2 sisters have been admitted to hospital and have developed syndromes due to oxytetracycline-resistant staphylococci with the same chronological sequence of events (cases 5 and 6; and cases 1 and 12). In addition, the resistant organism was not isolated from the upper respiratory tract of the nurses and doctors in contact with the latter 2 sisters.

Dearing and Heilman (1953) treated gastro-enterocolitis due to resistant staphylococci by discontinuing the oxytetracycline and giving erythromycin, obtaining good clinical results and the elimination of the staphylococci from the bowel. However, they cite the finding of a strain of *Staph. aureus* resistant to erythromycin in a patient in whom this drug was used, and forecast that more resistant strains will develop. So it appears that

TABLE VI—RESISTANCE TO ANTIBIOTICS OF STAPHYLOCOCCI ISOLATED

disturbances of the host-parasite-drug relationship are not going to be overcome by finding new antibiotics.

Finland et al. (1954) raise a doubt about the value of erythromycin in staphylococcal diarrhoea, stating that in most of these cases the stopping of treatment with the offending antibiotic leads to fairly prompt cessation of diarrhoea, and the staphylococci clear readily from the stools, even when staphylococci are still being obtained from cultures of other infected materials. We cannot comment on the rate of clearance of this organism from the bowel; but, as cases 5 and 7 showed, *Staph. aureus* persisted for a considerable time (eight and five days respectively) as a pure growth on throat culture. In view of this we think it is probably advantageous to the patient to be given an antibiotic to which the organism is sensitive. The clinical management of the diarrhoea caused by resistant organisms is stated by Hofer and McCaskey (1954) to be extraordinarily difficult. However, Finland et al. (1954) have shown that the incidence of watery diarrhoea associated with the administration of oxytetracycline or of aureomycin can be materially reduced, although not entirely prevented, by decreasing the dosage of these antibiotics. They also draw attention to the precipitating effect of the administration of cathartics in producing this diarrhoea, and state that cathartics should be avoided.

We wish to point out that 2 of our patients developed syndromes due to a resistant staphylococcus, but on the elimination of this organism they had a second course of oxytetracycline with no ill effects (cases 10 and 21).

Dearing and Heilman (1953) state that in their locality it was only after several years' use of oxytetracycline and aureomycin that resistant strains of *Staph. aureus* were produced, but the resistant strains we have observed were found in the first fourteen months (from October, 1952, to December, 1953) of the use of oxytetracycline.

The resistance and sensitivity of the staphylococci to different antibiotics are shown in table vi. Of fourteen staphylococci isolated twelve were cultured to assess their resistance to antibiotics: they were all resistant to penicillin, aureomycin, and oxytetracycline; two were resistant to streptomycin in addition; and a further two were resistant to chloramphenicol in addition.

3 urticarial reactions were noted: one on the fourth day, one on the seventh, and one on the tenth. Case 47 had severe angioedema of face and eyes as well as an urticarial reaction. Johnston and Cazort (1953) report a case similar to this but with severe cyanosis of extremities, lips, and face; it developed on the eighth day of therapy, and the patient had had a previous course of oxytetracycline.

Transient erythema was observed in 4 cases, sometimes with mild pyrexia but with no throat lesions. The rash cleared in all cases within twenty-four hours, and usually there was no general upset. Throat cultures in 3 of these patients were negative. These signs were

observed from the eighth to the tenth day. It therefore seems that, although there are exceptions, syndromes caused by resistant staphylococci develop before the eighth day after the start of treatment (most commonly on the fourth or the fifth day) and syndromes due to drug sensitivity develop on the eighth day or later.

There were 2 deaths, and 2 children with the scarlatinal syndrome were sufficiently ill to cause anxiety. These 2 girls, sisters, had severe diarrhoea causing dehydration, and their throat lesions prevented them from swallowing; accordingly they needed intravenous fluids for several days. One of the deaths (case 1) was particularly tragic because the child was only a carrier of *Salmonella typhimurium* and on admission was clinically healthy.

This report emphasises that the broad-spectrum antibiotics are not without their dangers, all the more so because we do not yet fully understand the reasons for some of the upsets involved. Our mortality is 0.3%. Jackson et al. (1951), treating 91 pneumonia patients with oxytetracycline, observed diarrhoea in 37 cases, a resistant staphylococcus being the only, or the predominant, organism in 12 out of 18 cases in which cultures were attempted. It was thought that the staphylococcal gastro-enterocolitis might have been an important contributory factor in the fatal outcome of at least 3 of the 7 patients who died. We emphasise that the broad-spectrum antibiotics should not be used for trivial and minor illnesses.

Is the relative benignity of the side-effects we observed due to the fact that we used a smaller dosage than is generally used? Or do our local staphylococci possess invasive, pathogenic, or toxin-producing qualities different from those of brethren elsewhere? Or is it because most of our patients belonged to the younger age-groups and had not got debilitating disease? The answer to these and other questions lies in the search ahead of us.

Summary

An incidence of about 8% of side-effects was observed in 603 cases treated with oxytetracycline.

The side-effects were divided into those associated with coagulase-positive staphylococci resistant to oxytetracycline and those in which no resistant organism was isolated.

Broad-spectrum antibiotics should not be used in minor illnesses.

We wish to thank Dr. A. L. K. Rankin, physician-superintendent, Belvidere Hospital, for permission to publish; Dr. J. Ives, bacteriologist, Glasgow Royal Infirmary, Dr. Ian MacLean, bacteriologist, Belvidere Hospital, and Mr. Peter Douglas, senior laboratory technician, for their assistance; Dr. R. C. Curran for the two necropsies; and Dr. R. E. O. Williams, of the Staphylococcal Reference Laboratory, Colindale, for the phage-typing.

SEE-SAW RELATIONSHIP BETWEEN HYPERTHYROIDISM AND MYASTHENIA GRAVIS

BRUCE MACLEAN

NORTH STAFFS ROYAL INFIRMARY

HYPERTHYROIDISM with myasthenia gravis has rarely been reported. Rennie (1908) described the first recorded case in Australia and referred to previous publications by Meyerstein (1904), Loeser (1904), and Brissaud and Bauer (1905).

It was later realised, as pointed out by Brain and Turnbull (1938), that external ocular paresis in association with thyrotoxic myopathy was often confused with myasthenia gravis in the past. Doubt must therefore be cast on all reported cases in the absence of confirmatory neostigmine tests. Allowance must also be made for the observation by McEachern and Ross (1942) that thyrotoxic myopathy itself shows a limited neostigmine response. Thus Thorner (1939), listing 24 reported cases, could find only 7 where the diagnosis was beyond doubt. It has been suggested that Rennie's original case was really one of exophthalmic ophthalmoplegia with thyrotoxic myopathy (Cohen 1946).

In proved cases of the combination of these two diseases there has been considerable divergence of findings as regards the effect of anti-thyroid treatment on the signs of myasthenia gravis. Partial thyroidectomy has either relieved or cured the myasthenia gravis (Kowallis et al. 1941, Thorn and Eder 1946, Sheldon and Walker 1946). Bartels and Kingsley (1949) found in a series of 12,962 cases of exophthalmic goitre 4 with complicating myasthenia gravis; they considered that anti-thyroid treatment produced no change in the myasthenic picture.

On the other hand, a "see-saw balance" between the two conditions has been described, the signs of myasthenia gravis increasing as the signs of thyrotoxicosis diminish, and vice versa. Thorner (1939) recorded a case of myasthenia gravis where the onset of thyrotoxicosis was attended by a lessening in the myasthenia, and radiotherapy of the thyroid gland made the myasthenia worse. Carrying his trial further he found that the myasthenia gravis improved under treatment with thyroid extract, but at the expense of inducing thyrotoxicosis. Thyroidectomy has been shown by Cohen (1946) and McEachern and Parnell (1948) to worsen the myasthenia gravis; and thiouracil therapy has been shown by Thorn and Eder (1946), Cohen (1946), and McEachern and Parnell (1948) to increase the myasthenia gravis. Greene (1949) has also pointed out the see-saw balance.

The case presented here shows clearly the see-saw relationship between these two conditions.

Case-report

A woman, aged 29, first reported to the medical outpatient department in August, 1948, with four months' history of illness. Three months after a normal confinement she had developed typical thyrotoxicosis, with sweating, tremors, nervousness, weakness, loss of weight, diffuse thyroid enlargement, and bilateral exophthalmos. Her doctor started treatment with methyl thiouracil 300 mg. a day for four weeks followed by a maintenance dose of 100 mg. a day. In eight weeks the patient had gained 7 lb. in weight and was feeling much steadier, but her thyroid had become larger. At that time, however, she developed a drooping of the right eyelid, more pronounced at the end of the day, when her legs felt weak and she had difficulty in swallowing. It was because of the ptosis that she was referred initially to the eye department, and thence to the medical outpatient department. Her mother had developed at puberty non-toxic thyroid enlargement, which has persisted until now. A sister in 1950

had thyrotoxicosis necessitating thyroidec-tomy. Two other siblings are alive and well. On examination the patient was well built, with moderate bilateral exophthalmos but no clinical signs of thyrotoxicosis. There was ptosis of the right upper eyelid, more pronounced after repeated movements. Vision was normal, and nothing abnormal was detected elsewhere in the body. A Wassermann reaction was negative, and a radiograph of the skull was normal.

Treatment.—A test dose of neostigmine 1.5 mg. by injection abolished the ptosis completely for an hour. Thiouracil was therefore discontinued, and two or three tablets daily, each containing prostigmine 15 mg., were sufficient to control the signs of myasthenia gravis.

November, 1948.—The patient had again begun to lose weight, with signs of thyrotoxicosis, the plasma-cholesterol level being 135 mg. per 100 ml. Exophthalmos was more severe, and there was constant diplopia, with paralysis of the left superior oblique muscle. The pulse-rate had risen to 122. An injection of neostigmine 1.5 mg. caused retraction of the previously ptosed lid to a greater extent than on the other side, exposing a band of sclera. Potassium iodide gr. 6 daily was given with little or no improvement in the thyrotoxic picture.

January, 1949.—Thiouracil was again exhibited in full dosage. Within six weeks the thyrotoxicosis was satisfactorily under control, but the myasthenia gravis had become extreme, with drooping of both eyelids, general weakness, and slurring of the speech.

May, 1949.—Thiouracil was again discontinued, and the myasthenia gravis gradually improved at the expense of a mild recurrence of thyrotoxicosis. Radiography of the chest showed mild bilateral tracheal compression. The urinary excretion of creatinine was 176 mg. per 100 ml., the plasma-cholesterol level was 155 mg. per 100 ml.; a glucose-tolerance test was normal, and the basal metabolic rate (B.M.B.) was +29%. Small doses of thiouracil were given in an attempt to strike a balance but had to be reduced when the myasthenia became more severe.

January, 1950.—The B.M.B. was +18%, and plasma-cholesterol level 300 mg. per 100 ml.; diplopia was still present, but evidence of thyrotoxicosis was minimal. Thiouracil therapy was again stopped.

March, 1950.—Thyrotoxic signs had reappeared, and for a fourth time thiouracil was used, with resultant control of the thyrotoxicosis and a worsening of the myasthenia gravis.

April, 1950.—Small doses of thiouracil were again given.

August, 1950.—Thiouracil treatment was stopped. The patient's appearance in October, 1950, is shown in fig. 1.

January, 1951.—Thyrotoxicosis was again manifest. Thiouracil was given once again, with improvement in the thyrotoxicosis and increase in myasthenia.

Fig. 2.—Effect of treatment on combined thyrotoxicosis and myasthenia gravis: note see-saw relationship.

From June, 1951, the requirements of neostigmine, which was originally instituted in September, 1948, decreased progressively. Although a further course of thiouracil was given in November and December, 1951, myasthenia gravis did not recur. The effect of the treatment is shown in fig. 2.

February, 1952.—The patient appeared to have achieved natural recovery, and she has needed neither thiouracil nor neostigmine since then.

Follow-up.—Neither thyrotoxicosis nor myasthenia gravis has recurred. The patient's present condition is good. The exophthalmos persists, together with slight ptosis of the right upper eyelid. The patient's appearance in September, 1953, is shown in fig. 3. Eye movements are full, and the patient's weight is steady. The thyroid enlargement has regressed slightly.

Discussion

McEachern and Parnell (1948) have classified the neuromuscular disorders that may complicate thyrotoxicosis as follows:

- (1) Exophthalmic ophthalmoplegia, with oedema, fatty infiltration, and swelling of the extraocular muscle-fibres.
- (2) Acute thyrotoxic encephalomyopathy, presenting with bulbar palsies and relieved by anti-thyroid measures (Waldenström 1945).
- (3) Chronic thyrotoxic myopathy, characterised by weakness, wasting, and fasciculation of voluntary muscles.
- (4) Familial periodic paralysis.
- (5) Myasthenia gravis.

The present case and previously published cases (see table) supply apparently contradictory evidence about the effect of anti-thyroid treatment on myasthenia gravis. It seems therefore relevant to consider in detail the diagnostic criteria upon which the differentiation is

--	--

It has been held that bulbar palsies do not occur in thyrotoxic myopathy (Greene 1949), yet acute thyrotoxic encephalomyopathy does, and Laurent (1942) records 2 cases of severe thyrotoxicosis in which pronounced dysphagia, dyspnoea, and weakness, relieved by neostigmine, developed a week or two before death. Creatinuria, thymic enlargement, and lymphocytosis are common to both conditions. In myasthenia gravis the myasthenia is more severe at the end of the day, and the eyelids droop, whereas in thyrotoxicosis they are retracted. It seems not impossible, however, that myasthenia may relax the levator palpebrae spasm.

Response to neostigmine is usually held to be pathognomonic of myasthenia gravis, yet neostigmine has been observed to relieve the myasthenia in thyrotoxic myopathy (McEachern and Ross 1942, Waldenström 1945), and this cannot therefore be used as an undisputed means of differentiation.

Myasthenia in association with thyrotoxicosis may be divided into two main groups :

(1) Thyrotoxic myasthenia responds to neostigmine and is relieved or cured by anti-thyroid treatment.

(2) *Myasthenia gravis* is in most cases relieved by the onset of thyrotoxic symptoms and made worse by anti-thyroid measures. Thymectomy sometimes improves it (Greene 1949, Carson and Keynes 1942). They show a definite see-saw relationship between thyrotoxicosis and myasthenia gravis, the one waxing as the other wanes.

The present case is therefore clearly one of myasthenia gravis, being produced at will by initiating anti-thyroid treatment, and resembling the case reported by Thorner (1939), who achieved remission of myasthenia gravis with thyroid extract at the expense of inducing thyrotoxicosis.

The muscular weakness and easy fatigability in myasthenia gravis are due to a muscular metabolic defect

leading to failure in chemical transmission at the neuromuscular junction, where normally acetylcholine is liberated. The administration of the anticholinesterase neostigmine, by protecting acetylcholine from destruction, rapidly alleviates the symptoms. Normal blood and muscle cholinesterase levels have been obtained in such cases, and the cause must be either deficient production of acetylcholine or the presence of a curare-like substance. If such a substance does exist, the cuff experiments of Walker (1938) would indicate that it is locally produced by muscular activity. A raised blood-thyroxine level either diminishes the production of, or inactivates, such a curare-like substance, leading to improvement in the myasthenia.

The rôle of the thymus in myasthenia gravis is obscure. It has often been found enlarged, but its size seems to have no bearing on the duration or the extent of the clinical picture according to Carson (1942). Keynes (1949), reporting on 120 survivors of thymectomy who did not have tumours, showed that 65% were virtually cured, 25% improved, and 10% unchanged. The improvement, however, is gradual, and may take a year before the optimal benefit is received.

Thyrotoxic myasthenia responding to neostigmine must be presumed to have a similar differential aetiology. No cuff experiment seems to have been done here, and the constant level of the myasthenia through the day argues a central rather than a local cause. Perhaps a constantly high blood-thyroxine level causes deficient production or rapid destruction of acetylcholine at the motor nerve-endings, thus resulting in myasthenia.

The coincidence of myasthenia gravis and malignant exophthalmos in the absence of thyrotoxicosis reported by Zondek and Ticho (1951) seems to incriminate the pituitary gland, and both conditions were in fact improved by X-ray therapy to the pituitary region. We therefore make the following suggestions :

(1) That thyrotoxic myasthenia is due to rapid destruction or defective production of cholinesterase at the myoneural junction, secondary to a high circulating thyroxine level.

(2) That myasthenia gravis is due to a curare-like substance produced locally at the site of muscle activity, and inactivated or not produced when the blood-thyroxine level is high.

(3) That there is a direct inverse relationship between the thyroid and the thymus glands, probably both under influence of the pituitary gland.

(4) That the action of the thymus gland in the production of myasthenia gravis is still obscure and appears to be secondary.

Summary

A case is presented showing the typical "see-saw" relationship between thyrotoxicosis and myasthenia gravis.

Such a relationship is always present when these two conditions are found together, and surgical intervention must therefore be regarded as dangerous.

The condition is self-limiting, and in the present case a middle course was steered between the exhausting effects of both diseases by the intermittent use of thiouracil.

Myasthenia coincident with thyrotoxicosis may be either thyrotoxic myasthenia or true myasthenia gravis. Anti-thyroid measures have directly opposing effects in these two conditions, relieving the thyrotoxic myasthenia and worsening the myasthenia gravis.

A possible mechanism by which myasthenia is produced in these diseases is suggested.

BOTH the urgency and the extent of the optimal surgical treatment of acute hæmatogenous osteitis have been sharply disputed for over twenty years (*Proceedings of the Royal Society of Medicine* 1932). The introduction of penicillin, which made possible remarkable control over staphylococcal infections as a whole, intensified this controversy. Wilkinson (1951) remarked that the question whether the administration of penicillin should be accompanied by extensive emergency surgical procedures "could be settled with certainty only by a large series in which alternate patients were operated on. Experience is still fallacious and judgment difficult even after the advent of the antibiotics."

We describe here a trial planned to decide this question. The trial covered three years from January, 1949. At that time there seemed to be considerable differences between the practice of different groups of experienced workers. Agerholm and Trueta (1946), Trueta and

Agerholm (1948), and Tucker and Hollenberg (1948) held that penicillin treatment had not eliminated the need for extensive emergency surgery, but that incision of the abscess and drilling of the affected bone could be followed by primary closure of the wound. Dennison (1948) had advocated a similar procedure, without drilling of the bone. By contrast, Altemeier and Helmsworth (1945) and Altemeier and Wadsworth (1948) had decided that "emergency surgical intervention is usually unnecessary" in cases adequately treated with penicillin; they believed in allowing a clinically demonstrable abscess to form, which could be evacuated days or weeks after admission. Aird (1946), Hudson (1946), and Wilkinson (1948) appeared to agree broadly with this more conservative approach. Most conservative of all, Higgins et al. (1947) claimed that, in children, it was necessary only to aspirate pus which "formed outside the bone," at an unspecified stage of the disease. Unfortunately we felt unable to accept their conclusions at that time, because more than half their patients were less than a year old, several had already been ill for some weeks at the time of admission, and the small doses of penicillin which they recommended suggested that they had been dealing with relatively mild cases.

We found it impossible satisfactorily to assess the relative merits of these two contradictory schools of thought, because of two main omissions from their reports: there was no clear clinical definition of the type of cases treated, and the evidence did not suffice for realistic and objective comparison of the results. We therefore decided to treat a consecutive series of suitably defined cases alternately by Trueta's method and by a more conservative method (calling the two treatment groups "drilled" and "conservative"), and to try to find a satisfactory criterion for assessing and comparing the results.

Our trial was planned to supply the answers to the following three practical questions:

1. What are the clinical indications for local intervention to remove pus?
2. Where indicated, how urgent is this local intervention?
3. Should the local intervention consist in incising the abscess and drilling the affected bone, or can an open operation be avoided altogether?

Methods

SELECTION OF MATERIAL

We felt strongly that the cases for inclusion in the trial must be carefully selected from the full range of cases of acute osteitis admitted to hospital, with two main requirements in mind: (1) our series must be sufficiently uniform for comparison of results between one case and the next to be valid; and (2) the question of surgical treatment must be a real issue in every case, both so that the trial should be really critical and so that there should be no ethical objection to operation if so indicated by our method of random selection.

We selected for the trial all cases which on admission satisfied the following criteria:

- Age: 2-12 years.
 Grade: severe (see below).
 Duration on admission: 48-168 hours.
 Bone involved: major long bone of a limb.
 Treatment before admission: no antibiotics.
 Organism: sensitive to penicillin.

The lower age-limit was set at 2 years in accordance with the views of Green (1935); and although we do not fully agree with these views, our original decision proved satisfactory for the purposes which we had in mind. The upper age-limit was determined by the fact that our experiment was confined to cases in the children's wards.

Grade was judged in terms of a clinical classification of the disease which we had devised for ourselves, for lack of a satisfactory one in published reports. This classification will be described fully elsewhere, together with the details of the 96 cases of acute osteitis admitted during the trial. The severe case over the age of 1 month is defined as one in which

all the essential symptoms of the disease are fully developed within 72 hours of the onset of pain. These symptoms are taken to be: complete disability of the affected limb, pain sufficient to interfere seriously with sleep, complete anorexia, malaise sufficient to suppress all interest in recreation of any kind, and obvious feverishness. Of 50 consecutive such cases, delirium occurred in half and vomiting in a third; their temperatures on admission were 101°-107°F, and the blood-culture on admission was positive in 30. Possibly our mild cases (in which these symptoms never became fully established, or did so after more than 72 hours) correspond roughly with the "subacute" cases of some workers (*Proceedings of the Royal Society of Medicine* 1932, Dennison 1948). Such cases were excluded from the trial because we knew that in them rapid recovery could be expected with penicillin alone, without any local intervention.

Duration.—Those whose penicillin treatment was started within 48 hours of the onset were excluded for the same reason. (Of 14 such patients only 1 required local intervention.) Those whose illness was of more than a week's duration on admission were excluded because we felt that after this stage the nature of the surgical treatment was unlikely materially to affect the local lesion: the prognosis was known to be very bad, and we hoped that there would be too few such cases for purposes of comparison. Only 1 case had to be excluded on these grounds; this was a severe case of acute osteitis of the humerus of 15 days' duration, in which the abscess burst through the skin on the evening of admission.

Only *major long bones* were included because the surgical problems raised by osteitis of small and flat bones are very different, and are often individual to the particular bone.

Patients who had had any significant *antibiotic therapy* before admission were excluded because their inclusion would have introduced a variable factor which we could neither control nor allow for properly in the final assessment.

The *sensitivity of the organism* had to be defined because penicillin was regarded as an essential part of the treatment: only 1 case had to be excluded because of a resistant organism (*Staphylococcus aureus* resistant to 2000 units per ml.).

By this method of selection the number of cases included in the trial was 31 of a total of 96 cases of acute osteitis seen during the 3 years. This could hardly be described as the "large series" called for by Wilkinson (1951); but we believe it to be a far more informative series, in relation to the questions which we were trying to answer, than a much larger unselected series would have been.

The selected cases were allotted on admission alternately to one of the two treatment groups—"drilled" and "conservative"—according to the next available symbol on a chart prepared with a statistician's advice.

ASSESSMENT OF RESULTS

Our second major problem was to devise a satisfactory way of measuring the success of treatment, so that the results in our two treatment groups could be objectively compared. The method of radiographic comparison used by Agerholm and Trueta (1946) was rejected as insufficiently precise, and of doubtful relevance to the patient's welfare provided the end-result was satisfactory. The criteria described (*Proceedings of the Royal Society of Medicine* 1932) were rejected as irrelevant to cases treated with penicillin in adequate dosage. We eventually decided to try to measure the effect of the operative treatment (or lack of it) on the duration of the disease, by recording the number of days which elapsed after admission to hospital until the patient was allowed to use the limb normally, without splints (always provided that the decision to allow full activity was vindicated by satisfactory subsequent clinical and radiographic progress during a reasonable follow-up period). McAdam (1945) had published this information about some of his cases.

This method appeared to have the advantages that the result could be expressed numerically; it was an expression of what mattered most to the patient; and, above all, it was a fact and not a personal impression. Of course personal judgment did enter into the decision to allow full activity; but the decision in each case was made

by the same group of three people and in accordance with well-defined clinical and radiographic signs (Neligan and Warrick 1953), so that there was a high degree of uniformity and minimal scope for any unconscious personal bias. The method appeared to us to be satisfactory in practice. In 1 "drilled" case (table I, case 9) infection recurred two weeks after the patient was first allowed to walk; a further period of restricted activity was necessary, and the duration of disability was reckoned to the end of this second period.

When it came to the final assessment, however, it was clearly unrealistic to compare the results in a weight-bearing bone, such as the tibia, with those in the arm-bones or fibula; so the series was ultimately reduced to the 23 cases in which the femur or the tibia was involved. This need had been foreseen, and the chart used for allocating the selected cases to the two treatment groups on admission was designed accordingly, with separate subgroups for each bone.

General Management

The penicillin therapy and general management of the cases in the two treatment groups was identical in all respects, except for minor differences implicit in the different surgical techniques:

Penicillin.—50,000 units intramuscularly was administered 3-hourly for 21 days at least, and thereafter until the bone was free of tenderness and the erythrocyte-sedimentation rate (E.S.R.) was decreasing steadily and had reached about 20 mm. in 1 hour (Westergren).

Intravenous Therapy.—Plasma, blood, or electrolyte solutions, as indicated, were given in 2 "drilled" and 3 "conservative" cases.

Immobilisation was achieved by padded plaster back-splint or a sling in all cases where it could make the patient more comfortable. To avoid disuse osteoporosis, such immobilisation was stopped as soon as the limb was free of pain and any wound was healed. But in 5 cases the limb was put into a plaster cast when the patients were sent home at the end of the course of penicillin, because we thought that these patients were unlikely to keep off the leg voluntarily until we gave permission for weight-bearing.

Free Activity.—The decision to allow this depended on a satisfactory clinical condition and certain radiographic criteria (Neligan and Warrick 1953). Absence of any decalcification within 28 days of the onset, or the first signs of recalcification in previously decalcified areas, were taken to indicate that a fracture need not be feared. The only exception was case 14 (in the "conservative" group), where decalcification was so gross that we waited for the third set of films showing recalcification before regarding the tibia as safe for weight-bearing.

Surgical Treatment

In the "drilled" group the surgical treatment was that described by Trueta and Agerholm (1948). But we have subsequently found out (Trueta 1952) that in two details our technique differed from that used by these workers:

1. In many of our cases the wound was not examined until the 10th day after operation, when the stitches were removed. This omission, however, does not appear to have been directly related to delay in healing; and a hæmatoma was evacuated on the 4th day in the only case where the wound broke down completely and required secondary suture (case 12).

2. In 9 of the 12 cases interrupted catgut sutures were used to approximate the periosteum or the muscle sheath, or both, before closing the skin. This procedure was very definitely related to delay in healing of the wound (see table I); but in no case did this delay cause postponement of weight-bearing. Trueta states that he too had noted this tendency of buried catgut to interfere with the healing of the wound, and had eliminated periosteal sutures from his technique some years previously.

In the "conservative" group, by contrast, there was no detailed description of any accepted method of local treatment for us to follow. Table II shows that in the first 5 cases in this group we failed to achieve the objective of avoiding open operation. In these 5 cases aspiration was omitted or done in a way which we now regard as

half-hearted and ineffective; but the operation was confined to incision of the periosteum and evacuation of the underlying pus, followed by suture of the wound. When once we had realised that the subperiosteal abscess could be adequately emptied by thorough aspiration, carried out as soon as possible and repeated if necessary, the whole picture altered. We were able, by this means, to avoid operation in 4 of the last 6 cases (the remaining 2 required no local treatment for the evacuation of subperiosteal pus). A further 15 similar cases have since been treated satisfactorily by aspiration alone.

Where indicated, we now carry out the first aspiration within hours of starting penicillin treatment. The patient is given an appropriate dose of sodium quinalbarbitone ('Seconal Sodium') orally and morphine hypodermically about three-quarters of an hour before the aspiration. With a full aseptic technique, and using autoclaved instruments, a short, wide-bore needle (a "taking" transfusion-needle, B.S.W.G. 13, 3.5 cm. long,

has proved suitable and convenient) is plunged through the tissues into contact with the bone at the site where the abscess is judged to be maximal; the thick pus may flow out slowly under pressure, or may need to be aspirated. If no pus is found at the first attempt, the needle is withdrawn slightly and reinserted down to the bone at a different angle. Where the abscess is very extensive we have thought it wise to aspirate it at two separate sites, to ensure adequate emptying; but this may not be necessary at subsequent aspirations, when the material is more fluid. A small dressing is placed over the puncture-hole for a few hours afterwards. We have not injected penicillin into these abscesses; but when an infected joint has been aspirated penicillin has been injected in the usual way (cases 14 and 21).

The unequivocal indication for initial local intervention is, we believe, the presence of a subperiosteal abscess; but we have not found it necessary to wait for the formation of an abscess demonstrable on ordinary

clinical examination, as suggested by Altemeier and Wadsworth (1948), nor does our experience in case 14 suggest that it is safe to do so.

The difficulty is that it is usually impossible to detect fluctuation on ordinary clinical examination when the pus is in a tense collection deep to the exquisitely tender periosteum. But we know that a subperiosteal abscess is likely to be present in any severe case of acute osteitis where penicillin treatment has not been started within 48 hours of the onset of pain. If, in such a case, the tenderness extends along the shaft of the bone well beyond the limits of the affected metaphysis, with swelling of the overlying tissues, we act on the assumption that an abscess is present; for our experience suggests that this extension of tenderness is usually produced by extension of pus deep to the periosteum. If the patient is then examined under heavy sedation, so that tenderness is eliminated, the fluctuation is usually detectable. In this way the presence and the position of the abscess can be determined with certainty in the great majority of cases and the site of the aspiration planned accordingly. Failing this, we have been guided by the area of greatest tenderness, and have not failed to find the abscess with the aspirating needle since our first case.

We have repeated the aspiration as often as a fluctuant collection of fluid reaccumulates, or until the aspirated material is sterile on culture. Detection of fluctuation is much easier after the initial aspiration both because the tissues are less tense and tender and, we believe, because some of the fluid is relatively superficial, having leaked out from beneath the periosteum through the holes made by the needle.

Comparison of Results

The results of the trial, set out in tables I and II, show no significant difference between the two treatment groups, judging by our main criterion: the average number of days from admission until free weight-bearing was allowed and found to be safe was 61 for the "drilled" and 64 for the "conservative" cases. Examination of the two groups for factors likely to affect the prognosis shows only one significant difference: the average duration on admission in the "conservative" group was, by chance, some 15 hours greater than in the "drilled" group. Judging by the average duration of fever and of penicillin treatment, there is again no significant difference between the two groups. The average duration of tenderness, however, was shorter in the "drilled" group (15 as compared with 21 days); but in no case did the tenderness persist long enough to affect adversely the general management of the case, and its distribution did not suggest persistence of metaphyseal infection. A preliminary survey of the radiographic appearances up to the present time does not show any clear-cut difference between the two groups except that the amount of subperiosteal calcification is certainly greater in the "conservative" cases in the early stages. This follow-up is being continued to see whether there is any difference in the time taken for the affected bones to regain a normal appearance. The fact that in each case successive radiographs are showing a steady return towards normal is our justification for publishing the results after such a relatively short follow-up period.

In 2 cases the period of disability was unduly long:

Case 9.—This patient in the "drilled" group had a clinical recurrence of infection, as already mentioned, 2 weeks after he was first allowed to bear weight. In retrospect, we may have made a mistake in stopping his penicillin treatment on the 32nd day, after his E.S.R. had risen from 30 to 37 mm. in 1 hour (Westergren) during the previous week; but his course of penicillin was longer than the average for the series. Although the recurrence settled well with penicillin and immobilisation, and no further period of restricted activity has been necessary, he had a minor recurrence a year later during which he spontaneously discharged a minute sequestrum, and penicillin-sensitive *Staph. aureus* was grown from

material aspirated from his tibia. He had a further minor recurrence, due to the same organism, another year later, and is regarded as a possible chronic case. This result is most unsatisfactory.

Case 14.—Our failure in this case in the "conservative" group, on the other hand, can confidently be attributed to our inexperience of the method. His operation was delayed for 9 days after admission, because of severe vomiting and diarrhoea among other factors; no aspiration was carried out during this period because we had not yet realised how much can be achieved in this way. This was the one case, therefore, in which an abscess obvious on ordinary clinical examination was allowed to develop, and in the light of subsequent experience we have no doubt that this avoidable delay in local intervention caused the gross decalcification of the tibia which occurred during the next 10 weeks; this was quite out of proportion to what we saw in any other case. This was also the only case in either group in which septic arthritis developed during penicillin treatment.

Conclusions

Any conclusions are applicable only to the type of case included in the trial. Some of the most difficult surgical problems in the treatment of acute osteitis arise in the newborn, and in older children whose lesion is in the neck of the femur; our results are not strictly relevant to these problems, since the newborn were deliberately excluded and only 1 older child with a lesion of the neck of the femur chanced to qualify for inclusion. But we think that the principles suggested by our results can be applied to these problems, and to lesions of short or flat bones.

We think that these principles, in terms of our initial questions, are as follows:

1. The clinical indications for local intervention are the signs of a subperiosteal abscess, as already described. Such an abscess is likely to be present in any severe case of acute osteitis where treatment has not been started within 48 hours of the onset.
2. When these indications are present it is a matter of some urgency to evacuate the pus, and we believe this should be done within 24 hours of admission or as soon afterwards as the abscess can be accurately located.
3. There appears to be no certain advantage in open operation with drilling of the bone. By the criterion we have used, the results are as good in cases treated by thorough aspiration of the subperiosteal pus, repeated when necessary. This result is not inconsistent with the finding that a subperiosteal abscess cannot be completely emptied by a single aspiration (Agerholm and Trueta 1946, White and Dennison 1952). That the aspiration may help indirectly, by allowing escape of pus into the soft tissues, is suggested by case 4. At operation 3 days after a single aspiration, no frank pus was found; but we saw a half-inch rent in the periosteum and some bloodstained seropus in the soft tissues.

Since our experience did not suggest any essential difference in the results likely to be achieved on the one hand by extensive emergency surgery and on the other by aspiration of pus, we felt free to base our choice on a comparison of the intrinsic merits and convenience of the two methods. The more conservative method has the advantages that a major operation under general anaesthesia is avoided; that there is no risk of the troubles associated with slow wound healing; that the first aspiration can be made within a few hours of admission even in cases where the patient would not be considered fit for operation; and that the patient is left unscarred. The advantage of extensive emergency surgery is that, once the operation has been done, there is no more that can be done, and there is no need for daily reassessment of the local condition with a view to further local treatment (except such as is required by the wound). We decided in favour of the more conservative method, and the results have been satisfactory so far; but we feel that success with this method demands a high standard of clinical judgment, with daily reassessment, and may not be achieved consistently except in centres where many cases are seen.

Summary

A trial was carried out in the years 1949-51 to decide whether in the treatment of acute hæmatogenous osteitis in childhood administration of penicillin should be supplemented by extensive emergency operation.

Of 96 cases admitted to hospital under our care, 23 satisfied the criteria for inclusion in the trial. Consecutive cases were treated alternately: (a) by open operation, including drilling of the bone; and (b) by a more conservative method, in which we came to rely on aspiration of pus from the subperiosteal abscess as the sole surgical measure.

The main criterion for assessing the results was the duration of disability after treatment was started. By this criterion there was no significant difference between the results with the two methods, and no important difference was found in respect of any other criteria.

Because of its intrinsic advantages, we selected the conservative method for routine use; but its successful application depends on good clinical judgment and on daily reassessment in the early stages.

We thank all those colleagues, surgeons and pædiatricians, who made this study possible by allowing us to assume clinical responsibility for patients who would otherwise have been theirs, and particularly to Sir James Spence and Dr. Donald Court for their constant encouragement and help. Mr. F. D. Hindmarsh, Mr. J. D. T. Jones, and Mr. J. A. Key were kind enough to operate on three patients in such a way that they could be included in the trial. We have also received invaluable help and guidance, both in the planning of the experiment and the presentation of the results, from Mr. H. Campbell, B.A., F.S.S. Prof. J. Trueta's interest, and his willingness to spare time to discuss this work, have been of the greatest help.

RESISTANT VENTRICULAR TACHYCARDIA CURED WITH LARGE DOSES OF PROCAINAMIDE

R. E. LOVELACE G. DALAWELL WALKER
 M.B. Lond. D.M. Oxf., M.R.C.P.
 HOUSE-PHYSICIAN SENIOR MEDICAL REGISTRAR
 NORTH MIDDLESEX HOSPITAL, LONDON

It is now established that procainamide is superior to quinidine in the treatment of ventricular tachycardia. The effective dose, which varies considerably, is usually 300-800 mg. intravenously, but a few cases require larger doses. The case reported here illustrates the need for, and method of, administration of larger doses of procainamide than usual, and suggests that the speed of injection may be important.

Case-report

A man, aged 65, was admitted on Nov. 9, 1953, with a history of sudden onset of palpitations a week previously. These continued uninterrupted, and there was increasing dyspnoea. Two years before he had had a myocardial infarct, with subsequent angina of effort and attacks of similar palpitations lasting from two to ten minutes. He had chronic bronchitis. Before admission he had received without benefit oral quinidine gr. 6 thrice daily for five days, followed by digitalis folia gr. 1 twice daily for two days.

Fig. 1.—Electrocardiograms on admission.

On admission he had a regular tachycardia of 180 with signs of moderately severe congestive failure, and early cure was considered imperative. Electrocardiography showed ventricular tachycardia, so the following schedule of treatment was started: oral procainamide 1 g. four-hourly; rectal aminophylline 0.35 g. four-hourly; oral promethazine 25 mg. four-hourly; phenobarbitone gr. $\frac{1}{2}$ thrice daily; amylobarbitone sodium gr. 3 every night; and mersalyl 1 ml. intramuscularly on alternate days.

2nd day.—The heart-rate was regular at 164, and the arm-tongue circulation-time exceeded 60 sec. Intravenous procainamide 1000 mg. was given at 50 mg. a minute; and the pulse-rate and blood-pressure were recorded, and an electrocardiogram (c.r.4) was made with a standard portable electrocardiograph, at intervals of a minute. The pulse slowed to a minimum of 112 after 700 mg. of procainamide had been given, and the lowest systolic pressure was 100 mm. Hg.

3rd day.—The congestive failure had improved, and the circulation-time was 18 sec. Intravenous procainamide 1000 mg. at 100 mg. a minute was followed half an hour later by 1000 mg. at 200 mg. a minute. The pulse-rate before, between, and three hours after the injections was 160; and it slowed during each injection, reaching a minimum of 110 towards the end of the second injection. At that point the lowest systolic pressure (90 mm. Hg) was recorded.

4th day.—Intravenous procainamide 1600 mg. was given at 160 mg. a minute; the pulse-rate fell to 100 and the systolic blood-pressure to 60 mm. Hg, but within twenty minutes the pulse-rate rose to 130. A further 1200 mg. was injected at 50 mg. a minute, and the pulse-rate again fell to 100 and the systolic blood-pressure to 80 mm. Hg. Again this proved transient. After this large dose of 2800 mg. the patient complained of irritation of his back and was confused, becoming about an hour later euphoric, hyperkinetic, deluded, and hallucinated. This condition lasted until it was controlled with intramuscular amylobarbitone sodium gr. 6 and intramuscular paraldehyde 10 ml.

5th day.—The patient was greatly improved but remained euphoric, had transient diarrhoea, and was febrile. A leucocyte-count was normal, and stool culture was negative. Treatment with penicillin 250,000 units four-hourly was started.

6th day.—Intravenous procainamide 1500 mg. was given at 400 mg. a minute, and nodal rhythm was established at 80. The lowest systolic pressure (65 mm. Hg) was recorded a minute later. Nodal rhythm at 80 was still present thirty minutes later, and that heart-rate was maintained until the patient was discharged.

7th day.—A purpuric rash appeared on the patient's back, and oral procainamide was discontinued in favour of quinidine gr. 3 thrice daily. A leucocyte-count was normal, and platelets were plentiful in a film.

8th day.—Electrocardiography showed sinus rhythm.

12th day.—The patient was quite free from cardiac failure and got up; his erythrocyte-sedimentation rate was 16 mm. in 1 hr. (Westergren).

21st day.—The patient was discharged and told to continue taking quinidine.

Electrocardiography on admission (fig. 1) showed a rapid regular succession of ectopic ventricular complexes arising in one focus, probably posterior; the main deflection in c.r.4 (fig. 2a) was a wide slurred r wave. During the

Fig. 2—Successive changes in C.F.4 electrocardiograms on intravenous injection of procainamide: a, simple slowing; b, sporadic substitution by complexes arising from another focus; c, appearance of isolated complexes (probably nodal extrasystoles); d, nodal rhythm.

intravenous injection of procainamide the following changes were observed successively: (1) simple slowing (fig. 2a); (2) sporadic substitution by complexes arising from another (probably also posterior) focus (fig. 2b); (3) the appearance of isolated complexes (Q S lasting 0.1 sec. in C.F.4 [fig. 2c]), probably nodal extrasystoles by comparison with the next stage; and (4) nodal rhythm (fig. 2d). On the first two occasions (second and third days) changes 1 and 2 were noted; on the fourth day change 3 followed; and on the sixth day change 4 was reached. At no time was widening of the QRS complex observed. The final electrocardiogram showed evidence of old posterior infarction (fig. 3).

Comments

As previously reported by other workers, quinidine and oral procainamide failed, but intravenous procainamide eventually succeeded. The intramuscular route was not tried.

With proper precautions it was possible to give intravenous doses larger and faster than is usually recommended (1000 mg. in ten minutes). Minute-by-minute control was essential because individual tolerance varies and serious toxicity may develop with the minimal effective dose. 7300 mg. was given in five days, with a daily maximum of 2800 mg. and a maximal single injection of 1600 mg. Noradrenaline 4 µg. per ml. was immediately available in case of serious hypotension but was not needed.

The first injection was given at 50 mg. a minute (half the recommended speed). Later the dose and the rate

Fig. 3—Electrocardiograms showing evidence of old posterior infarction.

of injection were alternately increased. The final and curative injection, though not the largest, was the fastest (400 mg. a minute), and speed was considered an important factor in its effectiveness. Rapid injection increased the hypotensive side-effects, and there is evidence that it may delay intraventricular conduction excessively (Zapata-Diaz et al. 1952), but this was not seen here. We suggest reserving its use for cases proved resistant to injection at the usual rate. Use of direct-writing electrocardiography to detect widening of the ventricular complexes before fibrillation develops would improve the technique. The most troublesome side-effect was the hyperkinetic confusional psychosis which followed two successive large doses.

Rashes and fever have been reported following oral therapy, and there is evidence that they may be allergic. The promethazine already given may have modified their severity (Koffler 1953) in the present case. Agranulocytosis has also been reported, but we have found no previous observation of purpura with a normal leucocyte-count. Diarrhoea is also apparently a new finding.

Nodal rhythm has been produced experimentally (in dogs) with procainamide, and its transient appearance, as in the present case, noted before (Schoolman et al. 1953). It is probably due to direct suppression of the sino-auricular node.

Discussion

In resistant ventricular tachycardia intravenous procainamide appears often more successful than oral therapy (Antziz et al. 1952, Hanenson et al. 1952, and others), but oral quinidine in full doses may be as successful as oral procainamide (Antziz et al. 1952, Schaffer 1951). Schaffer states that the anti-arrhythmic activity of oral procainamide is from a quarter to a third of that of quinidine (equal absorption stated); and the rate of removal of procainamide from the blood-stream is twice as rapid as that of quinidine (Kayden et al. 1951).

In the present case the urgency did not permit trial of either massive quinidine therapy (gr. 2-6 each hour until toxicity was manifested) or intramuscular procainamide (*Lancet* 1952), either of which might have been successful.

In previous published reports the curative intravenous dose has been 300-800 mg., but some cases have needed more (Kelley et al. 1952, Schoolman et al. 1953) and some cases less—e.g., 60 mg. (Stearns et al. 1952). Our patient received 1000 mg. intravenously at 50 mg. a minute at first; next day 1000 mg. at 100 mg. a minute, this dose being repeated half an hour later at 200 mg. a minute; and the day after 2800 mg. an hour (1600 mg. at 160 mg. a minute and, after twenty minutes, 1200 mg. at 50 mg. a minute). After a day's rest 1500 mg. was given at 400 mg. a minute, ceasing immediately the pulse-rate fell to 80. The fact that speed increases the hypotensive side-effects has not been always found (Lucas and Short 1952, using smaller doses), and some workers also found that no better results followed rapid injection (Miller et al. 1951, using doses of 250-500 mg. at a rate of up to 500 mg. a minute). Further study of resistant cases treated with larger doses is needed. Two more disadvantages of rapid injection are the increased risk of intraventricular block (Zapata-Diaz et al. 1952) and the difficulty of close observation.

When procainamide is administered intravenously, the blood-procainamide level soon declines, perhaps 10-15% per hour (*Journal of the American Medical Association* 1950); and, as in previous reports (Miller et al. 1951, effect lasting from six minutes to two hours), we found its action on the heart transient, a second dose half an

hour later being little more effective than the first. With these larger doses we found speed to be relatively more important than size, but owing to the considerable dangers (cardiodepression and hypotension) involved in these methods, we would restrict such doses to very special cases.

As necessary precautions against hypotension, it is essential to observe the patient closely, measuring the systolic pressure every half-minute; to have antidotes ready (e.g., phenylephrine [Stearns et al. 1952]) and/or to take prophylactic measures (e.g., slow noradrenaline drip [Schoolman et al. 1953]). The other chief danger is the production of ventricular fibrillation. The cases for treatment can first be selected by excluding those with disease of the intraventricular conducting mechanism, because of the danger that procainamide may produce fibrillation, which may be fatal (Read 1952). Ideally progress should be observed by direct-writing electrocardiography so that any widening of QRS (recommended maximum 50%), with subsequent notching or prebrillary complexes (Denney et al. 1952), could be detected immediately and suggest caution or a halt. We merely observed the result of each injection in retrospect and, finding no such change, increased the rate and dose accordingly. Bifocal extrasystoles of ventricular origin (fig. 2b) were regarded with timidity, but the appearance of possible supraventricular complexes (nodal extrasystoles) was encouraging and suggested steady progress. It has also been suggested that the atrioventricular node is more sensitive to depression than the ectopic ventricular focus (Schack et al. 1952, Bernstein et al. 1952), but this suggestion seems to be in conflict with the appearance of nodal rhythm during cure.

As regards unavoidable toxicity, the acute confusional psychosis with prominent cerebral stimulation was not in agreement with previous experience (*Journal of the American Medical Association* 1950). This psychosis followed the administration of 2800 mg. of procainamide in an hour; so it is possible that blood-procainamide levels capable of stimulating the cerebral cortex may not have been reached before in man. In one case (Bakos and Askey 1952) restlessness and a desire to go home were manifested after oral procainamide 250 mg. had been given four-hourly for five doses.

Agranulocytosis and rashes have been reported following oral therapy with procainamide (Antzis et al. 1952), but the present case showed no blood disorder. However, immediately before the observation of petechiæ both in our case and in one reported by Antzis et al. (which later developed agranulocytosis) penicillin therapy had been started for pyrexia of unknown causes. This might have been only coincidental.

Pyrexia has been severe in some cases, and for both it and other toxic effects—e.g., urticaria, malaise, and nausea—an allergic basis has been suggested (Koffler 1953, Hellman 1952). In one case (Bakos and Askey 1952) pyrexia was specifically reproducible; in others it was associated with eosinophilia (Hellman 1952 and others) and responded to anti-histamine drugs. Intravenous procainamide given to two asthmatic patients produced convulsive movements and shock (Stearns et al. 1952). If promethazine had not been used in the present case, the temperature might well have risen higher than was observed here (100.4°F), and more side-effects than irritating purpura and diarrhoea might have developed.

Perhaps the fact that these effects follow oral procainamide mainly is reason for using quinidine as much as possible for oral curative therapy, and perhaps entirely for maintenance.

Conclusions

Intravenous procainamide should only be used in urgent cases and with the greatest possible precautions;

and higher doses and speeds of administration should only be used, and then cautiously, in proved resistant cases. The use of prophylactic anti-histamine drugs during procainamide therapy is desirable, and quinidine should be used for oral therapy where possible.

Summary

A case is reported of ventricular tachycardia with cardiac failure. After other methods had failed, cure was effected with intravenous procainamide given faster and in larger dosage than is usually recommended.

We wish to thank Dr. R. Kempthorne for permission to publish this case and for helpful criticism in the preparation of this paper; Dr. J. F. Heggie for his advice about the illustrations; Dr. L. A. Hamilton for his assistance and advice; and Mrs. I. P. Vedast for preparing the electrocardiograms.

A POTENT GROUP-O CELL-AGGLUTININ OF HUMAN ORIGIN WITH H-SPECIFIC CHARACTER

WINIFRED M. WATKINS

B.Sc., Ph.D. Lond.

BEIT MEMORIAL RESEARCH FELLOW

W. T. J. MORGAN

Ph.D., D.Sc. Zürich and Lond., F.R.S.

PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON
 From the *Lister Institute of Preventive Medicine*

SERA which agglutinate group-O and group-A₂ cells preferentially can be divided into two groups on the results of inhibition tests with saliva: those whose power to agglutinate such cells is inhibited by saliva from secretors belonging to any of the groups within the ABO system are designated anti-H, and those whose power is not inhibited are provisionally grouped together and called anti-O (Morgan and Watkins 1948).

It should, however, be realised that, although the latter sera are grouped together as anti-O, the results of inhibition tests with secretions from various sources, and the behaviour of the sera with the erythrocytes of group-O cord-blood (Watkins 1952), suggest that not all the sera classified as anti-O are of the same specificity. It is still not known which, if any, of these anti-O sera react specifically with the product of Bernstein's O gene.

Both O and H agglutinins are found among human sera; but anti-O sera are found more often. Both kinds of antibodies usually behave as cold agglutinins and are of low potency. The differentiation into anti-H and anti-O on the basis of inhibition by saliva is clear-cut, but it is impossible to distinguish between the two kinds of antibody on the basis of their reactivity with red cells.

A ₁ B	5	1	..	1	1	..	1
A ₂ B	2	1	..	1

Bhende et al. (1952) reported three examples of Indian blood with a "new" blood-group character related to the ABO system. The serum from each of the men contained anti-A₁, anti-A, and anti-B agglutinins, and the cells were not agglutinated by either anti-A or anti-B sera. Superficially, therefore, these men appeared to belong to group O, but their red cells were not agglutinated by human or by animal anti-H sera or by human anti-O sera, and their sera contained in addition group-O cell-agglutinins of greater potency than any which had hitherto been examined. Two of the sera gave a titre of 1 in 256 against group-O cells, and the third a titre of 1 in 32. Moreover these sera were active at 37°C, and the degree of agglutination was the same at 37°, 24°, 12°, and 5°C. The agglutination of group-O cells by each of the three sera was inhibited by saliva from group-O secretors; these sera were therefore classified as anti-H. The sera were not used to test the H-reactivity of red cells belonging to groups other than O, because of the presence of the anti-A, anti-A₁, and anti-B agglutinins. None of the three Indians secreted in their saliva A, B, H, or Le^b substances, but they secreted Le^a substance.

A further example of a human anti-H serum, "Warboys," has been encountered which differs in some of its properties from the Indian sera and anti-H sera of animal origin (Watkins 1952, Crumpton and Morgan 1953). The serum "Warboys" came from a group-B donor who did not secrete B or H substances in her saliva.

Serum "Tomlinson"

Recently an anti-H serum has become available to us which is considerably more powerful in its action on group-O cells than are the Indian sera. This serum was obtained from a woman, Mrs. Tomlinson, with carcinoma. The patient's blood-groups were A₁, Le (a-b-), CDe/cde, MNS, P+, Lu (a-), K-, and Fy (a+). Her red cells were not agglutinated by natural anti-H eel serum (Jonsson 1944), by immune anti-H serum prepared by the injection of rabbits with ovarian-cyst H-substance (Morgan and Waddell 1945), by natural cattle serum (Schiff 1927), by anti-H serum prepared by immunisation of chickens with *Shigella shigæ* (Grubb 1949), or by anti-O sera.

Treatment of the washed cells with saline at 56°C, however, yielded an eluate which agglutinated group-O cells to a titre of 1 in 64. It therefore seems that, although unagglutinated suspensions of Tomlinson's cells could be prepared in cold saline, they were nevertheless coated with a group-O cell-agglutinin which could be removed by washing with warm saline. The cells remaining after the antibody had been eluted were not agglutinated by either anti-O or anti-H sera.

Mrs. Tomlinson's saliva contained A substance, measured in inhibition tests against human anti-A serum, and H substance, measured against rabbit, eel, and cattle anti-H sera and human anti-H serum obtained from one of the Indians. Her saliva inhibited her own serum; unfortunately she died before a second sample of saliva could be obtained to confirm these findings. It was impossible to obtain blood and saliva specimens from any other members of her family.

The serum "Tomlinson" was titrated against the red cells of 65 group-O English people selected to include

Le (a-b+), Le (a+b-), and Le (a-b-) cells. All the bloods reacted strongly and gave agglutination titres ranging from 1 in 8192 to 1 in 32,768 at 25°C. The agglutination end-points were unchanged at 13°C and were lowered by only one or two tubes when the tests were made at 37°C. Absorption of the serum with either OLe (a+b-) or OLe (a-b+) cells removed completely the agglutinin reactive with all group-O cells. Agglutination of group-O cells by the serum "Tomlinson" was inhibited by saliva from group-O secretors, by purified H substance obtained from ovarian-cyst fluids (Annison and Morgan 1952), by hog H substance, and by meconium from group-O secretor babies. The serum was thus anti-H. The human anti-H serum "Warboys" was inhibited by meconium samples from babies who did not secrete A, B, or H substance in their saliva (Watkins 1952); the serum "Tomlinson," in common with the anti-H sera obtained from the Indians, was not neutralised by meconium from babies of the "non secretor" type.

A further point in which the serum "Tomlinson" behaved like the Indian anti-H sera and unlike "Warboys" was that it reacted with group-O cells from the newborn almost as strongly as with group-O cells from adults, whereas "Warboys" did not agglutinate cord-blood erythrocytes.

A sample of the serum "Tomlinson" was absorbed with A₁B Le (a-b+) cells until there was no further reaction with the absorbing cells. The absorbed serum was then titrated against 108 bloods belonging to different groups within the ABO system. The range of agglutination titres given by the cells is shown in table I. The absorbed serum gave consistently high titres with group-O and group-A₂ cells. Group-A₁ cells showed various degrees of reactivity, ranging from no detectable agglutination up to titres nearly as high as those given by group-O cells. In each of the six phenotypes within the ABO system, including group A₁B, samples were obtained which reacted with the anti-H serum; reactivity

Agglutination titres with unabsorbed serum "Tomlinson" given by group-A₁ cells from 112 people.

with the serum does not therefore depend on the ABO phenotype of the red cells, although it is evident that the ABO character has an influence on the degree of reactivity.

The serum "Tomlinson" came from a group-A₁ donor and was therefore free from anti-A or anti-A₁ agglu-

tinins and could be used to test the H-reactivity of group-A₁ cells without prior absorption or neutralisation of the serum; group-A₁ cells from one hundred and twelve people were titrated against the unabsorbed anti-H serum. Included in the samples were specimens from two unrelated group-A₁ donors who were of authentic genotype A₁A₁; both parents of each donor belonged to group A₁B. Authentic heterozygous group-A₁O cells from three donors were also included in the test. The titres obtained with the hundred and twelve samples are shown in the accompanying figure, and the results of titration of six specimens of group-A₁ cells are given in table II. The genotype of the donor (P.P. in table) whose cells reacted most weakly with the serum "Tomlinson" is unknown. The known homozygous group-A₁A₁ cells gave strong reactions at 21°C, whereas one of the heterozygous group-A₁O specimens (J.O'D. in table) showed considerably less reactivity. Since in a hundred and twelve group-A₁ bloods one would expect about fifteen of the genotype A₁A₁, many such bloods must be reacting more strongly than a known specimen of group-A₁O cells. The capacity of the cells to be agglutinated by the anti-H serum is therefore clearly not related to their homozygous A₁A₁ or heterozygous A₁O nature. Titration of serum "Tomlinson" with the weakly reacting cells from donor P.P. in albumin, or treatment with trypsin, did not increase the reactivity. Agglutination of the homozygous group-A₁A₁ cells could be inhibited by purified human H substance and was therefore due to the anti-H agglutinin in the serum and not to some other antibody. Further, the elution at 56°C of antibody absorbed at 0°C on to group-A₁A₁ cells from the serum "Tomlinson" gave an agglutinin which behaved qualitatively like the original serum.

One hundred samples of group-B cells were tested against a 1 in 5 dilution of serum "Tomlinson" after neutralisation of the β agglutinin in the serum with human B substance free from H activity. Only one specimen did not produce visual agglutination at this dilution. Titrated against the anti-H serum this sample gave a titre of 1 in 4.

Red cells from the Indian donor Z (Bhende et al. 1952) were not agglutinated by undiluted serum "Tomlinson" at 12°, 20°, or 37°C. Agglutination with the group-A₁ cells (P.P.), which reacted weakly at room-temperature, disappeared at 37°C but was intensified at 12°C. The cells from the Indian donor were therefore the only ones, among those tested, which appeared to be completely devoid of H activity.

The serum "Tomlinson" was not inhibited by the individual sugar components (2%) (L-fucose, D-galactose, N-acetylglucosamine, and N-acetylgalactosamine) of the human H substance as are certain other anti-H agglutinins (Watkins and Morgan 1952, Morgan and Watkins 1953).

Discussion

The group-O cell-agglutinin described here presents some unique features. It is by far the most powerful human anti-H serum that has so far been found and

shows a greater range of reactivity against cells belonging to groups other than O than is shown by animal anti-H sera. The agglutination given by homozygous group-A₁A₁ cells, and the weak reactivity shown with a sample of known heterozygous group-A₁O cells, leave no doubt that this powerful agglutinin is not detecting the product of the O gene despite its preferential reaction with group-O cells. Tanaka (1952) also concluded that the capacity of an anti-H serum (eel serum) to react with red cells did not depend on the presence on the cells of the product of the O allele. Another unusual feature is that the donor of the serum "Tomlinson" was a secretor of A and H substances; this finding is at variance with the suggestion of Sanger (1952) that anti-H and anti-O may be antibodies of the same general specificity, the former occurring in non-secretor persons. The possibility cannot be excluded, however, that the development of the antibody in this instance might be an immune response in some way connected with the patient's carcinoma.

The genetical relationship of H character to the ABO blood-groups is not yet clear. The serum "Tomlinson" will provide a most useful reagent for further investigations on the distribution and nature of the H-specific material on erythrocytes and in secretions.

Summary

A powerful group-O cell-agglutinin of human origin is described.

Its behaviour in inhibition tests with the water-soluble blood-group substances in saliva and purified H substance showed that it is an anti-H agglutinin.

The antibody reacts with authentic group-A₁A₁ cells more strongly than with a sample of known group-A₁O cells.

These results confirm that anti-H agglutinin does not detect a product of Bernstein's O gene, and that within the ABO system the homozygous (AA, BB) or heterozygous (AO, BO) nature of the cells cannot be determined by anti-H reagents.

We wish to thank Dr. Dorothy Parkin, of the Medical Research Council Blood Group Reference Laboratory, Dr. Adrian Slade, and the laboratory staff of the County Hospital, York, for allowing us to investigate this serum; and Dr. R. R. Race, F.R.S., and Dr. Ruth Sanger for advice and comments.

ADDISON'S DISEASE WITH DIABETES MELLITUS

A CASE TREATED WITH CORTISONE

IAN McLEAN BAIRD
M.B. St. And., M.R.C.P.

SENIOR MEDICAL REGISTRAR, ROYAL INFIRMARY,
SHEFFIELD

DONALD S. MUNEO
M.B. Aberd., M.R.C.P.

LECTURER IN THERAPEUTICS IN THE UNIVERSITY OF SHEFFIELD

THE coexistence of Addison's disease and diabetes mellitus is rare. Unverricht (1926) first described a case of diabetes in which the insulin requirements decreased rapidly with the development of Addison's disease. Soffer (1948) found only fourteen authentic cases published. In eight of these Addison's disease developed after the diabetes, in four the diseases appeared simultaneously, and in only two did Addison's disease precede diabetes.

A constant feature of cases of Addison's disease with diabetes mellitus is their extreme instability (Crampton et al. 1949). They are especially liable to develop hypoglycæmic attacks, which may cause death, as in the case described by Rhind and Wilson (1941).

The present case is an instance of diabetes mellitus in which the insulin requirements decreased considerably as Addison's disease developed. Treatment with cortisone, in addition to producing a striking improvement in the symptoms of Addison's disease, has increased the daily insulin requirements to near their former level and has greatly improved control of the diabetes.

Case-history

A housewife, now aged 42, enjoyed good health until the age of 23, when she developed diabetes and was stabilised on diet and 60 units of soluble insulin daily. Although she had a stillbirth at the age of 28, she later had two normal pregnancies at 34 and 38. Her mother and her twin sister both have diabetes mellitus. She remained well until her last pregnancy, when a gradual reduction in insulin dosage became necessary because of frequent nocturnal hypoglycæmic attacks. In a year the dosage decreased from 60 to 24 units of soluble insulin daily. Pigmentation of the skin, which developed during pregnancy, did not clear after delivery, and in the following two years the patient became progressively less energetic, her weight fell, and her appetite steadily decreased. She had occasional prostrating bouts of vomiting, sometimes associated with diarrhoea. In spite of continued reduction in insulin dosage the hypoglycæmic attacks persisted and the pigmentation deepened. A patch of intra-oral pigmentation developed.

On admission to hospital in July, 1952, physical examination revealed much wasting and extensive cutaneous and buccal pigmentation. The blood-pressure was 80/60 mm. Hg.

Investigations.—The serum-sodium level was 130 m.eq. per litre, serum-potassium level 5.3 m.eq. per litre, and fasting blood-sugar level 160–450 mg. per 100 ml. The urinary excretion of 17-ketosteroids in twenty-four hours was 1.5 mg. A blood-count showed Hb 86%, red cells 4,200,000 per c.mm., white cells 5000 per c.mm. (polymorphs 65%, eosinophils 2%, lymphocytes 26%, monocytes 7%). Radiographs of chest and abdomen were normal. Electrocardiography showed low voltage in leads I and a VL; flat T waves in leads I, II, III, a VL, a VF, V₄, V₅, and V₆; inverted T waves in V₁, V₂, and V₃; and prolongation of the S-T interval. The erythrocyte-sedimentation rate was 5 mm. in 1 hr. (Westergren). A Kepler test was abandoned because the patient could not drink the requisite volume of water without vomiting.

Treatment with added salt, injections of crude cortical extract, and deoxycortone acetate somewhat improved her general condition; but, as this was still poor, she was given oral cortisone acetate 25 mg. daily. After the second dose her urine became heavily loaded with sugar and ketone bodies. Since nausea, vomiting, and progressive drowsiness ensued, it was evident that she was on the verge of diabetic coma, and

only with difficulty was her diabetes again brought under control. After this the cortisone was withheld and 100 mg. of deoxycortone acetate implanted subcutaneously. With this treatment, the addition of 6 g. of salt to her diet each day, and restabilisation of her diabetes on 6 units of soluble insulin daily she improved slightly. After discharge she soon deteriorated once more, and her weight fell to 5 st. 4 lb. over the next year, a loss of 2 st. 10 lb. She had almost complete anorexia and was apathetic and depressed. It was felt that she was unlikely to survive many months.

Readmission to hospital was arranged in August, 1953. The signs of Addison's disease were unchanged, and her general condition was much worse. The investigations were repeated with similar results, except that the electrocardiographic abnormalities were more extensive (fig. 1a). The glucose-tolerance test is discussed below.

Treatment.—It was decided that a second attempt to introduce cortisone therapy must be made, starting cautiously with only 5 mg. daily. Accordingly this dose was started on Sept. 7, 1953. There was an immediate increase in insulin requirements from 6 to 16 units daily. By three-hourly urine testing and frequent blood-sugar estimations it was possible to make adjustments in insulin therapy promptly. Once the diabetes was stabilised, the dose of cortisone was increased to 10 mg. daily, whereupon more insulin was required. There-

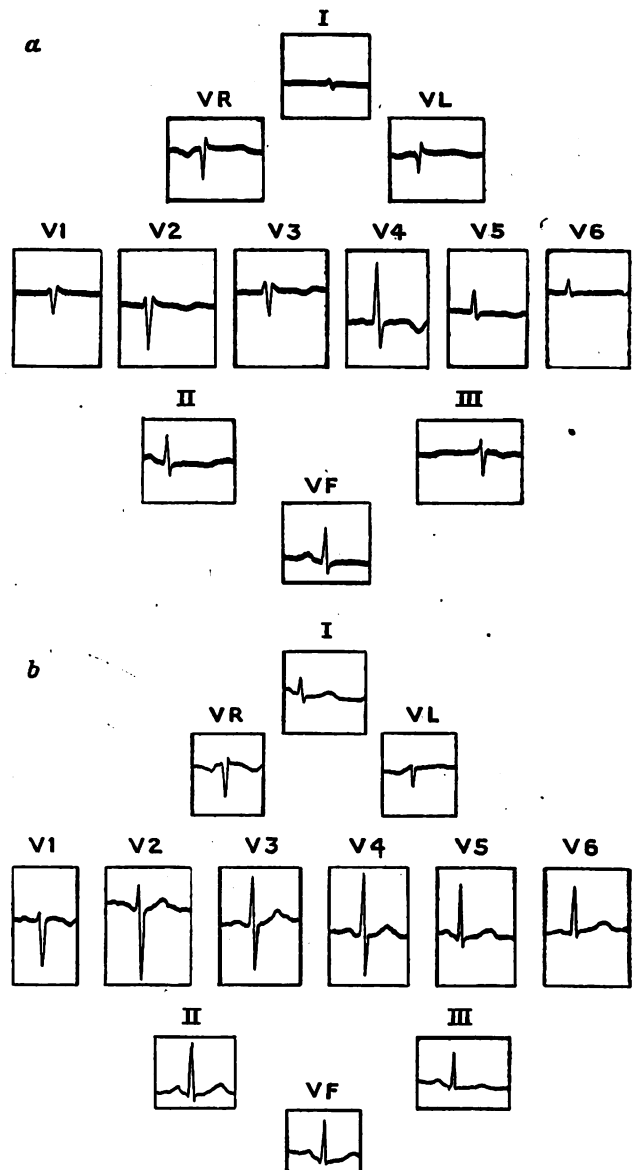

Fig. 1—Electrocardiographic changes produced by cortisone: a, a week before starting cortisone therapy; b, after two months' treatment with cortisone.

after cortisone was increased to 12.5 and finally to 25 mg. daily, by which time the insulin dose had risen to 48 units a day. These effects are illustrated in fig. 2. During this period there was a striking improvement in the patient: her apathy vanished, she regained her appetite, her general energy increased, and her weight increased.

Follow-up.—After five weeks in hospital she has been at home for three months, making steady progress while doing her own housework and caring for her two children. The improvement can be well seen in the two photographs (fig. 3). She weighs 7 st. 6 lb., her blood-pressure is 110/60 mm. Hg, her fasting blood-sugar level is 100–140 mg. per 100 ml., and her electrocardiograms have reverted to normal (fig. 1b).

Comparison of Diabetogenic Properties

This patient presented a rare opportunity for attempting a comparison between the diabetogenic powers of cortisone and of hydrocortisone. Oral cortisone is fully effective in four hours; therefore blood-sugar curves obtained from glucose-tolerance tests done at this interval after doses of either cortisone or hydrocortisone could be compared with control tests.

Because of the profound disturbance of carbohydrate metabolism resulting from small doses of these substances we could not administer increasing doses interspersed with days on which they were omitted for control tests,

Fig. 2—Effects of cortisone therapy on insulin requirements in Addison's disease with diabetes mellitus.

because this would have made control of the diabetes mellitus impossible.

For these reasons the following procedure was adopted :

(1) Control glucose-tolerance tests were made in duplicate before treatment was started. The results are shown in fig. 4a.

(2) A glucose-tolerance test was repeated four hours after oral administration of cortisone 5 mg. This was compared with the effect of hydrocortisone 5 mg. given next day. The result is shown in fig. 4b. It will be seen that the curve ran at a higher level after hydrocortisone.

(3) Once cortisone therapy was started with 5 mg. daily and the necessary adjustments in insulin dose were made, the dose of cortisone was raised to 10 mg. On the first day of the new dose a glucose-tolerance test was done, and a second test was done next day four hours after 10 mg. of hydrocortisone; cortisone

Fig. 3—Patient: a, before cortisone therapy; b, after three months' cortisone therapy, showing striking improvement in her general condition.

was omitted on this day. This gave a pair of curves contrasting the effect of 10 mg. of both substances (fig. 4c).

(4) Finally, when the time came to raise the dose to cortisone 25 mg. daily, a fourth pair of glucose-tolerance tests were completed, the first test after hydrocortisone 25 mg. (given instead of cortisone 25 mg.) and the second after cortisone 25 mg. (fig. 4d). In this way pairs of curves were obtained on successive days, contrasting the effects of 5, 10, and 25 mg. of both drugs, and these could be compared with the tests before treatment. Cortisone preceded hydrocortisone in the first two dosages; the reverse order was used in the third. The effects are illustrated in fig. 4. Hydrocortisone seems to be more diabetogenic than cortisone, apart from the last pair of curves in which there is little difference between the two; by this time the patient was already maintained on cortisone 12.5 mg. daily, and extreme sensitivity to these hormones had been lost. The blood-sugar estimations were done by the method of Hagedorn and Jensen.

Discussion

The alterations in carbohydrate metabolism that take place when a patient with diabetes develops Addison's disease have been described by Crampton et al. (1949). In Addison's disease there are a low fasting blood-sugar level, hypersensitivity to insulin, and defective storage of glycogen (Allott 1953). These effects, which are reversed by cortisone, accounted for the decrease in insulin requirements of our patient and for the abrupt increase on starting cortisone. After this second successful introduction of cortisone therapy it can be seen that the administration of cortisone 25 mg. would create an

Fig. 4—Glucose-tolerance tests after 50 g. of glucose given by mouth at 0 hours: a, two tests without previous administration of hormone; b, after cortisone 5 mg. and after hydrocortisone 5 mg.; c, after cortisone 10 mg. and after hydrocortisone 10 mg.; d, after cortisone 25 mg. and after hydrocortisone 25 mg.

urgent need for large additional doses of insulin, and this adequately explains the rapid development of diabetic ketosis when cortisone was given in 1952.

These events closely resemble those reported by Simpson (1953) in a similar patient, in whom diabetic precoma resulted from the administration of cortisone 25 mg. daily for three days. This patient was stabilised on cortisone 12.5 mg. daily after the daily insulin needs had increased from 12 to 74 units.

Thorn et al. (1951) describe two cases treated with cortisone by subcutaneous implantation, later supplemented by oral cortisone, but no comment is made on the rate at which insulin requirements increased. The return of the electrocardiograms to normal after cortisone therapy agrees with the observations of Somerville et al. (1951).

Summary

A case of coexistent diabetes mellitus and Addison's disease is described. As the Addison's disease developed, the insulin requirements decreased. Cortisone therapy initially precipitated diabetic ketosis, but later a more cautious introduction of cortisone was successful. Clinical improvement ensued although insulin requirements increased abruptly. A tendency to develop frequent hypoglycaemic attacks was eliminated.

Experiments were made to compare the diabetogenic properties of cortisone and hydrocortisone.

We wish to thank Dr. H. P. Brody and Prof. E. J. Wayne for permission to publish this case and for their helpful advice, and Mr. Ernest Salvin for the blood-sugar estimations. Part of the expenses were defrayed by a grant from the Tuberculosis Research Fund of the University of Sheffield.

TRANSFERENCE OF PASSIVE IMMUNITY FROM MOTHER TO YOUNG

F. W. ROGERS BRAMBELL	JOAN BRIERLEY
D.Sc. Lond., F.R.S.	B. Sc. Wales
RONALD HALLIDAY	W. A. HEMMINGS
B.Sc. Wales	B.A. Oxf'd

From the Agricultural Research Council's Unit of Embryology, University College of North Wales

In rabbits the transfer of passive immunity from mother to young occurs before birth (Brambell, Hemmings, and Henderson 1951b). There is no evidence that in this species any further transference occurs after birth, by way of the colostrum or the milk. It has been shown that transference in the rabbit is effected by the passage of antibodies from the maternal circulation into the uterine lumen and by their uptake from there by the yolk-sac of the foetus (Brambell, Hemmings, Henderson, Parry, and Rowlands 1949). Thus it is the inverted yolk-sac wall, covered with entoderm and vascularised by the vitelline circulation, which is the absorptive organ in the foetal rabbit, and not the allanto-chorionic placenta, as had been assumed previously (Brambell et al. 1951b).

The passage of antibodies into the foetus in rabbits can be studied conveniently by injecting immune serum directly into the uterine lumen, thereby avoiding complication due to passage from the maternal circulation to the uterine lumen (Brambell et al. 1949). The inverted yolk-sac wall and the chorion, forming a wide annular

zone, which is non-vascular, between the margin of the yolk-sac and the circumference of the placenta, are exposed to the immune serum in this way. The use of a mixture of immune sera, prepared in two or more species against a different antigen in each case, permits of direct comparison of the absorption of the different antibodies (Brambell, Hemmings, Henderson, and Rowlands 1950; Brambell, Hemmings, Henderson, and Oakley 1952). It was shown by this means that antibodies prepared in rabbits were absorbed by the yolk-sac wall and appeared in the foetal circulation much more readily than those prepared in cattle or horses (Brambell et al. 1952). Further work (as yet unpublished), in collaboration with Prof. C. L. Oakley and Mrs. I. Batty, has shown that antitoxins prepared in man, guinea-pig, and dog form a series in that order intermediate between those prepared in rabbits on the one hand, and in horses and cows on the other hand, in reference to the ease with which they are absorbed into the foetal circulation. Thus absorption by the yolk-sac is a selective process distinguishing between antibodies prepared in different species.

Antibodies from immune sera injected into the uterine lumen in pregnant rabbits also appear in the amniotic fluid of the foetus, having traversed presumably the non-vascular chorion and the amnion. Passage of antibodies from the uterine lumen to the amniotic fluid is not selective with reference to species of origin (Brambell et al. 1952). It differs in this respect from passage into the foetal circulation. Once within the amniotic fluid, antibodies can reach the foetal stomach, presumably through the gulping movements of the foetus, and may attain very high concentrations in the stomach contents. Nevertheless antibodies do not pass from the gut contents into the foetal circulation in rabbits in detectable amounts, whether they are prepared in rabbits or in other species (Brambell, Hemmings, Henderson, Oakley, and Rowlands 1951a).

It is well known that immunity is transferred from the fowl to the chick by way of the yolk of the egg. Passage of antibodies from the yolk into the circulation of the chick takes place during the later part of incubation (Brandly et al. 1946, Buxton 1952). It has been shown by one of us (J. B.) that immune serum can be injected into the yolk-sac on the 6th to 8th days of incubation and immediately after hatching and that antibodies from the serum can be absorbed into the circulation. Antibodies from immune serum prepared in fowl are absorbed readily, but those from sera prepared in rabbits, horses, or cows could not be detected in the circulation of the chick. Antibodies from serum prepared in pigeons were absorbed into the circulation in significant amounts, but less readily than those of immune fowl serum. Although the one-day-old chick can absorb antibodies from immune fowl serum injected into the retracted yolk-sac after hatching it cannot do so from the same serum administered orally, even before it has commenced to feed. The newly hatched chick resembles the foetal rabbit in that antibodies can be absorbed by the yolk-sac wall, but not by the gut wall, and absorption by the yolk-sac is a selective process distinguishing between antibodies prepared in different species.

In the rat, passive immunity is transferred mainly after birth by way of the colostrum and the milk. Moreover, transference continues for 20 days of lactation in this species. One of us (R. H.) has shown that when immune serum prepared in rats is administered by tube to the stomach the antibodies pass rapidly into the circulation of young rats at all ages from birth to 20 days. Antibodies of immune serum prepared in rabbits are absorbed from the gut into the circulation also, at least during the first 10 days of life, but much less readily than those from immune rat serum. Antibodies of immune sera prepared in cows or in fowl do not enter the circulation by this route in quantities that can be detected. Thus absorption of antibodies from the gut of the young

rat is selective, as is the absorption by the yolk-sac in the foetal rabbit or the chick.

In man transfer of passive immunity is known to take place mainly, or more probably entirely, before birth. The route is unknown, so far as we are aware. It has been assumed, though without evidence, to be by way of the allanto-chorionic placenta. This assumption is not justified any longer, in view of the discoveries outlined above concerning the route of transference in the rabbit. Yet the structure and arrangement of the embryonic membranes in man is entirely different from that in the rabbit. Transmission by way of the yolk-sac appears impossible, since this organ is rudimentary and is isolated from the periphery of the conceptus. Hence transference in man must take place by some other route than in the rabbit (Brambell, Hemmings, and Rowlands 1947). The late human conceptus is bounded by the placenta (chorion frondosum) and by the chorion laeve, consisting of the chorion to which, over almost its entire extent, the amnion is fused. Transmission of antibodies from the maternal circulation could occur either through the placenta directly into the foetal circulation, or by way of the chorion laeve into the amniotic fluid and thence by swallowing to the foetal gut. The former route appears at first sight to be the more obvious, but we know of no evidence to support it. Regarding the latter route we know that transfer is by way of the uterine lumen, not the placenta, in the rabbit (Brambell et al. 1949); that antibodies do pass into the amniotic fluid; that these are concentrated in the stomach contents of the rabbit foetus; and that antibodies are absorbed in quantity from the gut contents of newborn ruminants, horses, pigs, dogs, mice, and rats (Brambell et al. 1951b). It would be in keeping with our knowledge of other animals that the route in man should be via the chorion laeve, amniotic fluid, and foetal gut.

There is evidence that the absorption of antibody by the foetus in man is a selective process. Although the titre of the cord-blood of a newborn baby usually approximates to that of the blood of the mother, when she has been actively immunised, often equalling or even exceeding it, Hartley (1951) quotes two cases in which refined diphtheria antitoxin prepared from horse-serum did not pass from the maternal to the foetal circulation in significant amounts. Further, there is evidence that in haemolytic disease incomplete anti-D antibody reaches the foetus more readily than complete antibody (Pickles 1949). The selective absorption described above in the rabbit, fowl, and rat is mediated by an entodermal surface in each case, whether yolk-sac or gut wall. Absorption is selective in the guineapig also (Hartley 1951), but the arrangement of the foetal membranes in this animal is so similar to that in the rabbit that there is no reason to believe that the route of transference is different. It seems probable, if absorption is selective in man, that it occurs through an entodermal surface also and that the initial passage through the chorion laeve into the amniotic fluid is not selective. Concentration of antibody from the amniotic fluid in the stomach might occur, as in the foetal rabbit near full term (Brambell et al. 1951a). Should this be so, a considerable reservoir of antibody might be built up in the stomach contents, from which it might be absorbed into the circulation.

Medical Societies

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM

THE society's 74th annual congress was held on April 22-24 in Newcastle upon Tyne, under the presidency of Mr. ALEXANDER MACRAE. At the opening session, the Nettleship medal was presented to Dr. NORMAN ASHTON, director of pathology at the Institute of Ophthalmology, in recognition of his contributions to ophthalmology.

In the discussion on inflammatory vascular diseases affecting the eye, Mr. R. C. DAVENPORT considered in particular the condition of retinal vasculitis. He emphasised the frequent clinical association of these retinal vascular lesions with inflammation of the uveal tract; the condition was thus one that involved the major structures in the eye rather than a local vascular derangement. Dr. S. P. MEADOWS dealt with temporal arteritis. He had been impressed by how phlegmatic these patients were when confronted with sudden total blindness, an attitude which suggested that there was an associated general nervous degeneration. Other speakers confirmed this observation. Prof. J. B. DUGUID presented evidence to show that arterial occlusion was the underlying factor in various forms of acute arteritis.

Discussing the diagnosis of orbital tumours, Mr. GEORGE BLACK emphasised the value of radiography after air injection into the orbit. He preferred trans-frontal exploration rather than anterior biopsy when the tumour did not present anteriorly.

During the symposium dealing with the changes in the incidences of the eye affections of coalminers in the past twenty-five years, Dr. DOROTHY CAMPBELL discussed miners' nystagmus and pointed out the importance of accurate certification and of social welfare in preventing the condition. Mr. W. J. WELLWOOD FERGUSON presented statistics on the incidence and nature of ocular injuries from mining with general reference to methods of mining and methods of treatment and prevention. Dr. G. I. SCOTT drew attention to the declining incidence of hypopyon ulcers in miners during the past twenty-five years. This could be attributed particularly to the improvement of prophylactic treatment, given both as a first-aid measure at the pit-head and by the general practitioner.

A second symposium was devoted to gonioscopy after glaucoma operations. Mr. H. E. HOBBS illustrated the gonioscopic appearances after drainage operations, and assessed the clinical effects of the anatomical variants shown; and Mr. REDMOND SMITH discussed the general interpretation of broad and narrow angles and the presence of peripheral anterior synechiae.

In a series of short demonstrations, Mr. A. SEYMOUR PHILPS explained the technique of keratography and its value in recording irregularities of the corneal curvature; Mr. A. T. G. EVANS described a case of essential atrophy of the choroid with ataxia and a strong family history of similar conditions; Mr. J. FRANKENTHAL discussed a case of a large cyst of the iris following lens extraction; Mr. P. J. L. HUNTER described an unusual case of bilateral lymphosarcoma of the orbit; Mr. E. F. KING reported two cases of secondary carcinoma of the choroid, which had shown a striking regression after adrenalectomy; and Mr. P. D. TREVOR-ROPER described a case in which symmetrical metastases from a breast carcinoma had presented in the angles of both anterior chambers, strictly confined to the horizontal axes, suggesting an anatomical vagary of the retrobulbar arteries by which the metastases were diverted into the long posterior ciliary arteries rather than the short posterior ciliary arteries.

Reviews of Books

Child Health and the State

ALAN MONCRIEFF, C.B.E., M.D., F.R.C.P., J.F., Nuffield professor of child health, University of London. London: Oxford University Press. 1953. Pp. 48. 6s.

THE publication of Professor Moncrieff's Newsholme lectures will enable many who could not hear them to read and ponder over them with profit. He describes the evolution of the many services devoted to the promotion of health and happiness in childhood, and reviews the position of the local-authority services in relation to the National Health Service. He believes that the State is still not pursuing a sufficiently energetic child-health policy, particularly for the pre-school child. Nevertheless, it is a matter for pride that Newsholme's words are still true: "In no other part of Europe has there been such wide-spread and universal organisation of special work for the infant and pre-school child as in Britain."

Professor Moncrieff also believes that the great improvement in the health of school-children in the last fifty years has not been accompanied by sufficient adjustment of the school health service to present conditions. He regrets that provision for the care and education of the maladjusted child is still inadequate, and he rightly deplors the failure to continue the reablement and training of handicapped children after they leave school. The machinery for caring for the handicapped at this crucial age is there, but it is often ignored, and he emphasises the importance of enabling the physically handicapped child to remain at home whenever possible. Some of the provisions of the enlightened Children Act of 1948 have still not been implemented, and he particularly regrets the dilatoriness in establishing temporary reception centres which would spare deprived children from facing several changes before they are settled in suitable homes. But more and more deprived children are enjoying a happy home life rather than growing up in abnormal institutional surroundings.

His emphasis on the value of a closer liaison between parents and schools, and his belief that school doctors should take more part in school activities and instruction, are sound. There will also be general agreement with his view that still more could be done to help parents to accept responsibility for home care by encouraging them to overcome their troubles by living with them instead of passing them on to someone else, and with his timely warning of the increasing danger of parents demanding as a right to have everything done for them.

Physiopathology of Cancer

Editor: FREDDIE HOMBURGER, M.D., research professor of medicine; WILLIAM H. FISHMAN, Ph.D., research professor of biochemistry, Tufts College Medical School. London: Cassell. 1953. Pp. 1031. 135s.

IN his introduction to this weighty tome, Dr. C. C. Little emphasises the need to have at least a speaking acquaintance with the objectives, obstacles, and advances in all possible channels to progress. To meet this need the book not only covers research on the physiopathology of cancer, but goes much beyond its title and includes contributions from biology, chemistry, physics, clinical investigations, and practical applications. The durable value of some of the articles perhaps justifies the lavish production and high price.

Inevitably there is overlapping and even a little discord among the 28 contributors. Omissions of new work are unavoidable owing to the time-lag in publication. References extend only to 1951, with a few footnotes of later date. Recent successes in grafting heterologous tumours in the cheek pouch of the hamster, which will affect opinions on the immunological basis of grafting, are not included, nor is the reported action of cortisone in increasing metastatic growth. A more serious omission, not due to a time-lag, is a discussion of the subdivision of tumour induction into stages that have been described as initiation and promotion. This analysis of tumour genesis has practical uses as well as profound theoretical value.

But the excellence of many chapters outweighs any defects. The chapter on hormonal factors in experimental carcinogenesis may prove one of the most generally useful. The

chapter on steroid metabolism gathers together widely scattered and often discrepant data.

At present our only hope of reducing the amount of human cancer is by prevention, and only precise knowledge of environmental cancer will enable us to achieve this. This is the theme of a most informative section on occupational and other environmental factors. It is supported in another section by a lucid account of the problems of collecting and interpreting data and the help that can be expected from statistical studies. Well-balanced accounts of theories of carcinogenic mechanisms, chemotherapy, and radiation therapy, and an adverse review of diagnostic tests are included. The virus theory is dealt with in lively fashion, stress being laid on known instances of non-specificity of cell infection, thus making more plausible its universal application to all morphological varieties of cancer in all classes of animals. A section on epidemiology of spontaneous virus infections in avian flocks in the U.S.A. provides new observations on the time of appearance of antibodies to the Rous sarcoma virus in young birds and on the high incidence of antiviral antibodies to three varieties of infection in older ones. This information has long been wanting on both sides of the Atlantic.

Pulmonary Tuberculosis

Pathology, Diagnosis, Management and Prevention. 3rd ed. WALTER PAGEL, M.D., pathologist, Central Middlesex Hospital; F. A. H. SIMMONDS, M.D., physician and medical director, Clare Hall Hospital; NORMAN MACDONALD, M.B., M.R.C.P.E., physician, Clare Hall Hospital. London: Oxford University Press. 1953. Pp. 728. 84s.

THE general plan of presentation in this edition of Kayne, Pagel, and O'Shaughnessy's *Pulmonary Tuberculosis* is the same as in the last, but so swift have been the advances in the subject during the past five years that much of it has been rewritten—notably the sections on chemotherapy and surgical management, epidemiology, prevention, and B.C.G. vaccine. Dr. Nassau has again revised his chapter on bacteriological diagnosis. Yet the book remains the same size, and contains all the important facts. The quality of the many illustrations is high.

The authors' deep insight into the disease as a whole and into its natural progress has enabled them to maintain balance between the different aspects of the subject, and has clearly steadied them in their evaluation of such modern methods of treatment as lung excision—a radical measure which has still to win its long-term spurs. On the other hand, they are perhaps too severe in their criticism of the artificial pneumothorax, and possibly too lenient towards the pneumoperitoneum which has certainly felt the impact of chemotherapy and modern surgery much more than has the artificial pneumothorax.

Viruses

Symposia on Quantitative Biology. Vol. 18. Cold Spring Harbor Biological Laboratory. 1953. Pp. 301. \$8.00.

IF the textbooks contain solid fare, the Cold Spring Harbor symposia provide exotic and highly spiced dishes unsuited to tender digestions. In this instance there are 41 papers, mainly on bacteriophages, and to a lesser extent on animal viruses, and anyone who listened attentively to all 41 papers must have emerged sadder and perhaps wiser.

The papers are grouped as follows: virus in the vegetative state (i.e., in course of intracellular development) and its maturation, including recombination and multiplication cycles in bacterial and animal viruses; provirus (this is the state in which virus is assumed to exist in latent infections during which its development can be stimulated at any stage, although at the moment it cannot be identified in the provirus form); the transition from provirus to vegetative virus (both these groups of papers deal mainly with bacteriophages); structure of viruses; biochemical studies of virus infections; host-controlled variations of viruses; and, finally, the new and rapidly developing field of animal viruses in tissue culture.

This is a unique collection of essays containing a great deal of thought-provoking stuff, but it must be read in small doses, and certainly not in bed.

FAREX till five...

As soon as the infant weighs 15-lb., it is time for his introduction to Farex. Then it's Farex every day to take him smoothly on to "solids."

But remember, this sound start to nutritional well-being is best consolidated by giving the *balanced* nourishment of Farex throughout the early, formative years—right up until schooldays.

... and watch them thrive

GLAXO LABORATORIES LTD., GREENFORD, MIDDLESEX, ENGLAND

"F99" in the treatment of LEG ULCERS

CASE OF MR. B. S. Photograph on left taken 20th December, 1950, before treatment with "F99". Photograph on right taken 28th March, 1951, after 14 weeks' treatment with "F99".

"F99"—available in capsule, liquid and ointment forms—is a concentrate of the active isomers of Linoleic and Linolenic acids, of the highest achievable purity and standardized biological activity. It is indicated in skin disorders due to essential fatty acid deficiency of dietetic or "absorption" origin, i.e. chronic furunculosis, eczemas of various types, including infantile eczema, and in some cases of acne.

"F99" is also excellent in the healing of all wounds free from serious infection—particularly leg ulcers. Sufficient success has also been reported to warrant its use—as an unsaturated substance—in the treatment of psoriasis.

INTERNATIONAL LABORATORIES LTD. Dept. LT19, 205, HOOK ROAD, SURBITON, SURREY

FOCUS ON

Gastro-Enteritis

In the treatment of many infections of the gastro-intestinal tract, combined therapy with streptomycin and sulphaguanidine is a distinct advance on previous forms of treatment.

Guanimycin in which streptomycin sulphate is combined with sulphaguanidine is indicated for the treatment of gastro-enteritis, bacillary dysentery, summer diarrhoea, salmonella food poisoning and other mixed infections of the gastro-intestinal tract in infants, children and adults.

Guanimycin is issued as a stable dry powder from which a smooth, palatable, homogeneous suspension may be made by simple mixture with water.

GUANIMYCIN

Trade Mark

ORAL STREPTOMYCIN SULPHATE with SULPHAGUANIDINE

In bottles to prepare 4 fluid ounces.

Hazards of Broad-spectrum Antibiotics

ON an earlier page of this issue Dr. HAY and Dr. MCKENZIE describe the side-effects observed in the treatment of 603 cases with oxytetracycline (terramycin). Their patients under 12 years of age received 20 mg. per kg. of body-weight daily in four equal divided doses; those aged 12 years and over were given 2 g. daily. The drug was given with abundant fluids, usually milk, and vitamin B was also administered. Despite these precautions the incidence of side-effects was 8%; and 2 of the patients died with fulminating gastro-enterocolitis associated with coagulase-positive staphylococci. This considerable and well-documented series of observations brings home to us yet again that oxytetracycline, like other broad-spectrum antibiotics, must be prescribed cautiously. Apart from the 2 instances of fatal gastro-enteritis, HAY and MCKENZIE draw attention to other important staphylococcal complications of oxytetracycline therapy: sore throat with a scarlatiniform rash (7 cases); sore throat without a rash (8 cases); balanitis with scarlatina (1 case); and urinary infection (3 cases). The untoward effects in these 21 cases commonly appeared on the fourth or fifth day after the start of treatment. Not all of these 21 patients were examined bacteriologically, but staphylococci were isolated and incriminated as the probable cause in 14 of them. Other side-effects were observed in a further 31 cases: pyrexia (24); urticaria (3); and transient erythema (4). The 24 cases in which pyrexia was the only symptom were not examined bacteriologically, but the time of onset of the pyrexia coincided so precisely with that of the proven staphylococcal cases that there is at least a strong suspicion that the same organism was involved. The reports of the cases of urticaria and erythema read like the usual accounts of skin-sensitisation to antibiotics. Other reports of complications with the broad-spectrum antibiotics, from many sources,¹⁻⁵ combine to give a picture of antibiotic-resistant staphylococci stepping in to colonise the territory from which other bacteria have been eliminated, with rapidly fatal gastro-enterocolitis as a far-from-rare result.

What are we to do about this state of affairs? Clearly we must bring ourselves to understand that oxytetracycline, aureomycin, and the combination of penicillin and streptomycin are potentially lethal. In appropriate cases their use is justified; but we have to become more certain what is an appropriate case. HAY and MCKENZIE reasonably state that broad-spectrum antibiotics should not be used for trivial and minor illnesses. Nor should they be used for routine prophylaxis against infections which are far from inevitable and would be easily controlled if they
